**EDINBURGH BRANCH.**—The annual meeting of the Edinburgh Branch will be held at Pathhead Ford on Tuesday, June 26th. Luncheon will be provided in the Hall, Pathhead, at 12.15 for 12.30 p.m. (charge 4s.). Dr. Craig (Pathhead) has obtained the courtesy of the green of the Ford Valley Golf Club for the annual competition (stroke). He has also obtained the courtesy of the Pathhead bowling green. Visits have been arranged for Prestonhall Gardens, Crichton Castle, and Church, and the Vogrie Nursing Home, the latter by invitation of Professor G. M. Robertson. At 4.30 p.m. Dr. Craig will entertain the party to tea. The business meeting will take place at 5 o'clock. Agenda: Report of Branch, treasurer's business, and annual report; election of officers; representation of golf competition prizes; report of election of representative to the Central Council; filling of vacancy on the board of the Queen Mary Nursing Home; proceedings of Scottish Committee; Annual Report of Council and Annual Representative Meeting; Power of Branch to appoint additional members to Branch Council under Rule 4 (2) (g).

**METROPOLITAN COUNTIES BRANCH.**—The annual general meeting of the Metropolitan Counties Branch will be held at the British Medical Association House, Tavistock Square, W.C.1, on Tuesday, June 19th, at 4 p.m. Business: (1) Report of secretaries on election of officers; (2) Annual Report of Council; (3) report of representatives of the Branch on the Central Council; (4) presidential address by Dr. Christine Murrell entitled "Our changing times."

**METROPOLITAN COUNTIES BRANCH: HENDON DIVISION.**—A meeting of the Hendon Division will be held at the Hendon Cottage Hospital on Friday, June 29th, at 8.30 p.m., when members are invited to show cases. The meeting will subsequently discuss the Supplementary Report.

**METROPOLITAN COUNTIES BRANCH: LEWISHAM DIVISION.**—A meeting of the Lewisham Division will be held at the Town Hall, Catford, on Tuesday, June 19th, at 8.45 p.m. Mr. J. M. Redding will read a paper on some points in the x-ray examination of the alimentary tract.

**METROPOLITAN COUNTIES BRANCH: ST. PANCRAS DIVISION.**—A meeting of the St. Pancras Division will be held at the British Medical Association House, Tavistock Square, W.C.1, on Tuesday, July 10th, at 9 p.m. Dr. W. Camac Wilkinson will read a paper on the home treatment of tuberculosis by the general practitioner.

**METROPOLITAN COUNTIES BRANCH: WANDSWORTH DIVISION.**—Two meetings of the Wandsworth Division will be held in the Town Hall, Wandsworth, to consider the Koch diagnosis and treatment of tuberculosis by means of tuberculin, together with a proposal for a collective investigation into the subject. The first meeting will be held on Friday, June 22nd, at 9 p.m., when Dr. Robert Carswell will read a paper on "History and diagnosis." At the second meeting, on Friday, June 29th, at 9 p.m., Dr. Carswell will read another paper entitled "Treatment, and a proposal for a collective investigation." The meetings will be open to all members of the medical profession.

**METROPOLITAN COUNTIES BRANCH: WILLESDEN DIVISION.**—A meeting of the Willesden Division will be held at the Willesden Hospital, Harlesden Road, N.W., on Wednesday, June 20th, at 9 p.m. Dr. Margaret Enslie will discuss the care of the infant.

**NORFOLK BRANCH.**—The annual meeting of the Norfolk Branch will be held at the Town Hall, Aylsham, on Thursday, July 5th, at 3 p.m. Agenda: Report of the Branch Council and annual financial statement; induction of the new president, Dr. B. B. Sapwell, by the retiring president, Sir Hamilton Ballance, K.B.E., C.B.; election of officers; an address by Mr. Vivian Carter, British secretary of Rotary International, on the diagnosis of personality. Ten (to which ladies are invited) at 4.30 p.m. at the Grange, Aylsham, by invitation of Dr. Sapwell and Miss Sapwell.

**NORTHERN COUNTIES OF SCOTLAND BRANCH.**—The annual meeting of the Northern Counties of Scotland Branch is to be held at Kyle of Lochalsh on June 30th. This will be the first meeting of the Branch which has been held in the area of the Islands Division.

**NORTHERN COUNTIES OF SCOTLAND BRANCH: ISLANDS DIVISION.**—The general meeting of the Islands Division will be held on Saturday, June 30th, in the Station Hotel, Kyle of Lochalsh, at 10.30 a.m., to elect officers and Executive Committee.

**NORTH OF ENGLAND BRANCH: SUNDERLAND DIVISION.**—A meeting of the Division will be held at the Royal Infirmary, Sunderland, on Wednesday, June 20th, at 8.15 p.m. Among the matters to be considered at this meeting is the question of the adoption by the Division of a resolution on the scale of minimum commencing salaries for whole-time chief medical officers of health.

**NORTH LANCASHIRE AND SOUTH WESTMORLAND BRANCH.**—The annual meeting of the North Lancashire and South Westmorland Branch will be held on Tuesday, July 3rd, at 3.15 p.m., in the Ethel Hedley Hospital, Calgarth (by kind permission of Dr. Hough and the Governors of the Hospital). Dr. J. Lang Cochran will deliver his presidential address. Ladies are invited, and a boat on Lake Windermere will be placed at their disposal.

**NORTH WALES BRANCH.**—The annual meeting of the North Wales Branch will be held at the North Wales Sanatorium, Llangrffan, Denbigh, on Friday, July 6th. The council of the Welsh National Memorial Association and the house committee of the sanatorium will entertain the members to lunch, and a tour of the institution will be made. Agenda and further particulars will be announced later, but members are requested to make a note of the date as a large attendance is hoped for.

**OXFORD AND READING BRANCH.**—A meeting of the Oxford and Reading Branch will be held at the Holloway Sanatorium, Virginia Water, on June 27th.

**SOUTHERN BRANCH: PORTSMOUTH DIVISION.**—The annual business meeting of the Portsmouth Division will be held at the Queen's Hotel, Southsea, on Thursday, June 21st, at 9.30 p.m., preceded by a supper at 9 p.m. Agenda: Election of officers and committee; Honorary Secretary's report; alteration of Rule 5; Resolution.

That the Council's proposed methods of publicity concerning public education in health are not in the best interests of the profession; Portsmouth Hospital Contributory Scheme; report of the Representatives' Committee.

**SOUTHERN BRANCH: JERSEY DIVISION.**—A meeting of the Jersey Division will be held at the General Hospital on Thursday, June 21st, at 8.30 p.m. Dr. A. H. Jacob will read a paper on tuberculosis from the point of view of the tuberculosis officer.

**SOUTH WALES AND MONMOUTHSHIRE BRANCH.**—The fifty-eighth annual meeting of the South Wales and Monmouthshire Branch will be held at the Free Library, Victoria Gardens, Neath, on Thursday, June 21st, at 2.45 p.m. Agenda: Correspondence; Annual Report of Council and balance sheet for 1927; election of officers; installation of president; presidential address by Dr. J. M. Morris. The passing of the old family doctor. At the conclusion of the meeting, a visit will be paid to the National Oil Refineries at Llandarcy. The mayor, Councillor W. K. Owen, J.P., invites members to tea at Groll Grounds, Neath, recently purchased as a war memorial. If time permits some cases of interest to the general practitioner from the public health clinics will be shown by Dr. J. M. Morris.

**SOUTH-WESTERN BRANCH.**—The eighty-ninth annual meeting of the South-Western Branch will be held on Wednesday, June 27th, at 3.15 p.m., in Bromley's Café, Barnstaple, when Mr. Pickard will resign the chair to Dr. Harper, who will deliver his inaugural address entitled "The influence of William Smellie and William Hunter on obstetric medicine in the eighteenth century." The report of the Branch Council for the year 1927-28, and the financial statements of the Branch for the year 1928-29 will be presented to the meeting, and the Luncheon, by invitation of the President-Elect, will be taken at 1 o'clock at Bromley's Café, and after the meeting has concluded, tea will be provided. The annual dinner of the Branch, to which medical and non-medical guests and ladies are invited, will be

held at 7 o'clock at the café. Tickets, 8s. each (exclusive of wines), may be obtained from Dr. H. C. Jonas, Boutport Street, Barnstaple. Accommodation for the night could be arranged if notice is given to Dr. H. C. Jonas, Boutport Street, or Dr. Killard-Leavey, Litchdon House, Barnstaple.

**SURREY BRANCH.**—The annual meeting of the Surrey Branch will be held in the Town Hall, Kingston-on-Thames, on Wednesday, June 27th, at 2.15 p.m. The Kingston-on-Thames Division invites members to lunch at Nuthall's Restaurant at 1 p.m. Colonel C. W. Proffit will address the meeting on the British Empire Cancer Campaign in Surrey, and the president (Dr. H. R. Cran) will deliver his presidential address. After the meeting members will motor to Epsom to visit Epsom College; tea will be taken in Big School. The annual dinner will be held at Reid's Restaurant, Ashley Road, Epsom, at 6.30 for 6.45 p.m. (tickets 7s. 6d., exclusive of wines).

**SUSSEX BRANCH.**—The fifteenth annual meeting of the Sussex Branch will be held in the Royal York Hotel, Brighton, on Thursday, June 21st, at 2 p.m. Agenda: Election of officers; induction of president to chair; Annual Report and Financial Statement of Council; presidential address. The members of the Brighton Division invite other members intending to be present to luncheon at the Royal York Hotel, Brighton, at 1 p.m. In the afternoon cars will leave the hotel about 3 p.m. for Falmer, where Dr. Eliot Curwen will demonstrate a Romano-British Settlement at Buckland Bank. Tea will be provided at Falmer. Members are invited to bring their wives to this excursion.

**SUSSEX BRANCH: BRIGHTON DIVISION.**—The next clinical meeting of the Brighton Division will be held at the Royal Sussex County Hospital, Brighton, on Thursday, June 28th, at 3.45 p.m.

**WILTSHIRE BRANCH.**—The annual meeting of the Wiltshire Branch will be held on Wednesday, June 27th, at 3 p.m., at the County Mental Hospital, Devizes, when a British Medical Association Lecture will be given by Mr. W. McAdam Eccles on the treatment of hernia by trusses, illustrated by their actual application.

**WEST SOMERSET BRANCH.**—The annual meeting of the West Somerset Branch will be held at Deller's Café, Taunton, on Saturday, June 23rd, at 12.15 noon. Agenda: Induction of president-elect; annual report; election of officers, Branch Council, and Ethical Committee.

**WORCESTERSHIRE AND HEREFORDSHIRE BRANCH.**—The annual meeting of the Worcestershire and Herefordshire Branch will be held at the Hospital, Hereford, on Thursday, June 21st, at 3.15 p.m. Agenda: Report of Branch Council; election of president for 1929-30; election of honorary treasurer and secretary. Dr. Naish will vacate the chair and introduce his successor, Dr. Hincks. A clinical meeting will then be held. Dr. Naish invites all members of the Branch attending to have lunch with him at the Green Dragon Hotel at 1.30 p.m. After the meeting tea will be provided.

**YORKSHIRE BRANCH: HUDDERSFIELD DIVISION.**—The annual picnic of the Huddersfield Division will be on Thursday, June 21st. The charabanc will leave York Place at 12.15 p.m. for Dovedale. Afternoon tea will be served at the Peveril of the Peak Hotel on arrival at 3.30 p.m. The afternoon will be spent in Dovedale, and the charabanc will leave Dovedale at 5.45 p.m. for Buxton, where dinner will be served at 6.45 p.m. at the St. Anne's Hotel. The party will leave Buxton at 8 p.m., and should arrive in Huddersfield about 10 o'clock. The inclusive charge for charabanc, tea, dinner (exclusive of beverages), and tips, will be £1 2s. 6d. per head; for those going in their own cars 10s. per head.

## Meetings of Branches and Divisions.

### CONNAUGHT BRANCH.

The annual general meeting of the Connaught Branch was held at the Railway Hotel, Galway, on May 19th.

Honorary Secretary, Dr. John Mills  
Committee, Mr. M. G. O'Malley and  
Representative Body, Dr. John Mills.  
Body, Dr. E. S. Foley.

The Report of Council was considered and discussed.

### ESSEX BRANCH.

The annual meeting of the Essex Branch was held at the Palace Hotel, Southend-on-Sea, on May 24th, when Dr. KEVERN (Wivenhoe), president, was in the chair, and forty-five members were present.

The following officers were elected for the ensuing year:

President, Dr. T. Brice Poole. Past-President, Dr. G. T. Ke. Dr. J. F. Walker. Honorary

Dr. KEVERN, having in the presidential chair, passed on to

into the presidential chair and badge

PRESIDENT and to the HONORARY SECRETARY, both of whom briefly

replied. Dr. BRICE POOLE expressed his gratitude for the honour

that had been done him in electing him president for the year, and invited all the members present to take lunch with him.

The HONORARY SECRETARY presented the financial statement for the year, which showed that the Branch Fund had a balance of £44 4s. 6d., and the Private Voluntary Fund a balance of £10 9s. 11d.

Dr. WALKER drew the attention of the meeting to the great

needs of the B.M.A. Charities Fund, and proposed that £5 should, as in the previous year, be sent to the Charities Fund from the Branch Voluntary Fund. Dr. HAYNES seconded this proposal, and suggested that the amount should be increased to the whole of the Voluntary Fund, which was unanimously agreed.

Lunch followed the meeting, at the invitation of Dr. Brice Ponle, and afterwards members and their wives had a most enjoyable cruise in a motor yacht across the mouth of the Thames and up the Medway.

#### GLASGOW AND WEST OF SCOTLAND BRANCH.

THE annual meeting of the Glasgow and West of Scotland Branch was held in the Glasgow Royal Infirmary on May 30th, about eighty members attended under the chairmanship of Dr. R. M. BUCHANAN, president.

The annual report of the Branch Council was read and approved. The following office-bearers were elected for the ensuing year:

*President*, Dr. R. M. Buchanan. *President-Elect*, Dr. G. C. Crawford. *Honorary Secretary*, Dr. J. G. McCutcheon. *Vice-President*, Dr. James Hill and Dr. J. P. Brown. *Honorary Treasurer*, Dr. A. S. Richmond. *Auditors*, Dr. J. Wallace Anderson and Dr. George A. Allan.

After the annual meeting a clinical demonstration was given by the medical and surgical staff of the Glasgow Royal Infirmary, when many interesting and instructive cases were demonstrated.

On the motion of the CHAIRMAN a vote of thanks to the directors, medical and surgical staffs, and nursing staffs for their hospitality to the members of the Branch was heartily adopted.

At the clinical meeting a collection was taken for medical charities, which amounted to £14 8s.

#### NORTHERN COUNTIES OF SCOTLAND BRANCH.

A MEETING of the Northern Counties of Scotland Branch was held at the Lawson Memorial Hospital, Golspie, on May 19th, under the chairmanship of the vice-president, Dr. E. K. MACKENZIE. The chairman referred to the death of Dr. J. W. Mackenzie, and the secretary was instructed to send a sympathetic letter to Mrs. Mackenzie. The chairman also referred to the serious illness of Dr. T. Macdonald, the president, and the secretary was instructed to send him a telegram of sympathy.

Mr. B. S. SIMPSON gave a demonstration of surgical cases, including fragilitas ossium, nucocoele of the appendix, Paget's disease of the nipple, congenital megacolon, spasmodic torticollis, and two cases of extensive injury of the hand.

Dr. J. B. SIMPSON read a paper on general anaesthesia, which proved very interesting and instructive. Dr. Simpson said that his usual method was to induce anaesthesia by means of ethyl chloride administered in a closed mask, and then to continue the anaesthesia with a mixture of ether and chloroform by the open method. He described also the method of anaesthesia by nitrous oxide and oxygen, and of the administration of carbon dioxide in connexion with anaesthesia, emphasizing its value in cases where there was difficulty with respiration.

#### NORTHERN COUNTIES OF SCOTLAND BRANCH: ISLANDS DIVISION.

A MEETING of the Islands Division was held in the Royal Hotel, Stornoway, on May 30th, when members of the Isle of Lewis acted as hosts. After dinner Mr. POAVES, surgeon to the new Lewis Hospital, conducted the members on a tour of inspection of the hospital, which was followed by a discussion on various matters.

#### NORTH OF ENGLAND BRANCH: CLEVELAND DIVISION.

THE annual general meeting of the Cleveland Division was held at the Zetland Hotel, Saltburn-by-the-Sea, on May 17th. The annual report of the Executive Committee was approved.

The following officers were unanimously elected for the year 1928-29:

*Chairman*, Dr. James Brownlee. *Vice-Chairman*, Dr. H. Minnie Levick. *Representative in Representative Body*, Dr. John Inkster. *Assistant Secretary*, Dr. John the Maternity and Child Welfare Committee of Dr. John Howell.

The Middlesbrough and District Motor Club hospital insurance scheme was considered, and it was resolved that the secretary inform the club that the Division welcomed the scheme as an attempt to deal with the problem of the hospital treatment of motor accidents, but noted that the insurance covered maintenance only, and that their members would still be dependent on the charity of the honorary medical staff for their treatment.

Mr. H. D. Levick was appointed to represent the Division at a conference called by Sir Thomas Oliver to consider the question of the investigation of cancer in the northern counties. Dr. Dingle, the medical officer of health for Middlesbrough, notified the Division, through Dr. Levick, that he wished to make investigations into cancer in the town, and requested the help of members. It was resolved that members should notify Dr. Dingle voluntarily of any cases that came to their knowledge.

#### NORTH OF ENGLAND BRANCH: HEXHAM DIVISION.

THE annual meeting of the Hexham Division was held in the Abbey Hotel on May 25th, when Dr. FAIRCLOUGH was in the chair.

The annual report of the Executive Committee was received and approved, and the following officers were elected to serve during the ensuing year:

*Chairman*, Dr. Lloyd. *Vice-Chairman*, Dr. Turnbull.

It was agreed that the election of the representative and deputy

representative in the Representative Body (by the Consett Division) in the Hexham-Consett constituency be allowed to stand—namely, Drs. J. Charles and M. D. McKenzie.

A resolution that a voluntary levy of 5s. per member per annum be raised in defray cost of refreshments at meetings was carried. It was agreed to hold two summer meetings, one at Woolly Sanatorium and the other at Prudhoe Hall Colony for Mentally Defective Children, in June or July.

With regard to the inquiry into varicose ulceration treatment, five members expressed their willingness to reply.

The suggestion of the Council of the Durham University College of Medicine for a united endeavour of the Northern Counties to engage in the cancer campaign was approved, and the honorary secretary was elected to represent the Division at the proposed preliminary meeting.

#### NORTH WALES BRANCH: SOUTH CARMARVONSHIRE AND MERIONETH DIVISION.

A VERY successful meeting of the South Carmarvonshire and Merioneth Division was held at the Towyn Cottage Hospital on May 29th, when there was a good muster of members.

Previous to the meeting the members were entertained to lunch by Drs. H. P. ROWLANDS and J. A. DAVIES at the Corbett Hotel.

The Report of Council was considered, and it was resolved to ask the Representative Body not to adopt the recommendation for 8s. 8d. for attendance on juvenile members of friendly societies.

Dr. J. A. DAVIES showed cases of congenital claw-hand, paralysis of the hypoglossal nerve, and extensive ulceration of the legs. Dr. Davies also gave demonstrations of the x-ray and artificial sunlight apparatus at the hospital, and records of cases treated were shown. Dr. F. S. JACKSON showed a case of pseudo-hypertrophic paralysis (muscular).

At the conclusion of the meeting the members were entertained to tea by the matron of the hospital.

Altogether the meeting was one of the most pleasant functions in connexion with the Division in recent years.

#### OXFORD AND READING BRANCH: OXFORD DIVISION.

THE third meeting of the year of the Oxford Division was held at the Radcliffe Infirmary on May 23rd, when Dr. MONTGOMERY was in the chair and forty members were present.

The SECRETARY read a letter from headquarters about a demonstration of the handling of milk, and he was instructed to write and find out when and where this could be given.

Dr. A. G. WALTER (Wallingford) was unanimously elected an associate member of the Division.

Mr. BEVERS showed a woman, aged 39, where a large fibroid was causing the usual symptoms and signs, the best line of treatment.

Notes of a male patient, aged 39, who with symptoms referable to the left ureter was indefinite, but a pyelogram revealed obstruction of the left ureter by a small stone. The removal of which was followed by complete alleviation of the patient's symptoms.

Dr. F. G. CHANDLER contributed a paper on the early diagnosis and treatment of bronchiectasis. He first discussed the differential diagnosis between bronchiectasis and tuberculosis, chronic abscess, chronic empyema with a broncho-pleural fistula, foreign body or tumour in the bronchus, pressure on a bronchus, and syphilitic conditions. In the earlier stages a diagnosis had to be made on the symptoms and their history, the physical signs, bacteriological and pathological investigations, radiological examinations, and lipiodol injections. Many illustrative lantern slides were shown. The lecturer pointed out that frequently only an injection of lipiodol made an accurate diagnosis possible. Treatment was described under the following heads: the removal of obstruction; preventive treatment; general hygiene; diathermy; postural measures; creosote chamber; vaccines; medicinal treatment by inhalation, by mouth, by intratracheal injection; collapse methods—artificial pneumothorax, oleothorax; pleuric evulsion; pneumolysis, thoracoplasty, removal of the diseased area, and drainage.

#### SHROPSHIRE AND MID-WALES BRANCH.

THE fifty-third annual spring meeting of the Shropshire and Mid-Wales Branch was held at the Royal Salop Infirmary on May 25th, when the president, Dr. W. H. LEWIS, was in the chair. Reference was made to the loss occasioned by the death of Dr. James Wheatley, medical officer of health for the county of Salop, a member of the Branch Council, and a past-president of the Branch. The HONORARY SECRETARY having intimated that the coroner for Shrewsbury and district was entirely in favour of a payment of 10s. 6d. for reports on cases when an inquest or necropsy was not held, he was instructed to write to the county council on the matter. Mr. W. S. EDMOND, senior surgeon to the Royal Salop Infirmary, was elected to take office in October as the next president. The statement of accounts for 1927 was received and adopted. The Annual Report of Council was considered, and recommendations in regard to the following matters were approved: (1) infant hygiene centres; (2) fees for juvenile Odd-fellows; (3) report on puerperal morbidity; (4) report on lunacy certification; (5) ophthalmic benefit.

A Charities Committee was formed to consist of the president and honorary secretary for the time being, and Dr. Mackie. The members afterwards took tea at the kind invitation of the president.

## SOUTH WALES AND MONMOUTHSHIRE BRANCH.

The annual social meeting of the South Wales and Monmouthshire Branch was held at Pontefract on May 31st at the Taf Fechan Waterworks. The modern plant was examined in detail, and the various processes of water purification and filtering were demonstrated. After a motor run round the reservoir two and a half miles long, the party proceeded to Pontsarn Sanatorium, Welsh National Memorial Association, where they were received by the matron and Dr. D. A. Powell, principal medical officer of the association, and entertained to tea.

## ULSTER BRANCH.

The annual meeting of the Ulster Branch was held in the King Edward Memorial Hall of the Royal Victoria Hospital, Belfast, on May 17th, following a meeting of the McKisack Memorial Fund; an interesting series of clinical cases and pathological specimens was exhibited.

Dr. S. Moaog showed a case of pneumothorax, a case of aortic incompetence with mitral lesion, and a case of disseminated sclerosis with acute exacerbations and remissions. Professor Mellwaine exhibited radiographs of cardiac cases, a case of digitalis heart block, and one of exophthalmic goitre with auricular fibrillation. Dr. Foster Coates (Belfast) brought two patients with transverse myelitis, and one with abscess of lung. Dr. Boyd Campbell of enlarged spleen, one of subacute pulmonary infection with obstinate constipation, one showing fits associated with congenital syphilis, a specimen and radiograph of a case of aortic stenosis, and electro-cardiographic records from a case of influenza myocarditis. Dr. R. Maashall (Belfast) showed a case of bronchiectasis with cerebral abscess, one of persistent tremor of the thumb, one of splenic anaemia of fifteen years' duration, one of aortic aneurysm, one of aortic stenosis of uncertain origin, one of Hodgkin's disease with hemiplegia, an unusual case of general paralysis treated by malaria, and a mother and child with brachydactyly. Dr. Tunnicliffe (Belfast) demonstrated a case of coarctation of the aorta. Dr. Allen (Belfast) showed two cases of cretinism, a child aged 10 with acute rheumatic fever, mitral incompetence, and aortitis, a case of congenital heart disease, and one of dyspituitarism. Dr. M. J. Nolan (Downpatrick) showed a case of infantile face paralysis. Dr. Ivan McCaw exhibited some fine ringworm cultures. Sir Thomas Houston demonstrated some rough and smooth colonies of enterococci, and the reactions of *Staphylococcus deformans*. Dr. Eakin showed a case of goitre and parathyroid disease, a patient with paralysis of left arm following whooping-cough, and a case of interstitial keratitis. Mr. Mitchell (Belfast) showed a case of enucleation of the breast by Thomas's incision, and a case of tear of the right brachial plexus and fractured clavicle due to a motor cycle accident; there was complete loss of power and of sensation in the arm. Mr. T. S. Kirk (Belfast) presented a case of excision of knee-joint for chronic arthritis, and charts illustrating pneumonia treated by subcutaneous oxygen. Professor A. Fullerton exhibited a series of pyelograms, a case of haemorrhagic pancreatitis with recovery after operation, one of ureteral calculus without urinary signs, and one of ureteral implantation for ectopia vesicae. Mr. Howard Stevenson (Belfast) showed two cases of gastric ulcer on the posterior surface treated by excision, and a case of gastrectomy for carcinoma. Mr. S. T. Irwin showed cases of Erb's paralysis, two of congenital club-foot, one of Stoeckel's, one of pancreatic cyst, one of spontaneous fracture of ischium, and slides showing fractures involving the knee-joint. Mr. P. T. Cryan (Belfast) exhibited two cases of trigeminal neuralgia cured by division of the sensory root of the Gasserian ganglion, a chart indicating the causes of chronic gastric retention, a patient with an ulcer of the lesser curvature and a normal stomach picture who had been treated by hemigastrectomy; in it the radiogram was normal except that it showed some gastric retention, on which discovery was based a successful operation. Mr. H. P. Malcolm (Belfast) with Mr. Craig, showed a case of angioma. Professor R. J. Johnston and Mr. H. L. R. Grier (Belfast) demonstrated several gynaecological specimens. Mr. G. R. B. Bruce (Belfast) showed a case of carcinoma of the hepatic flexure ulcerating through the skin; the operation was performed in July, 1927. A diagnosis of appendicular abscess had been made. Mr. F. A. McLaughlin presented an unusual case of congenital syphilis and a case of double congenital coloboma iris. Dr. Evans exhibited some x-ray photographs of fracture of ilium, fracture of the skull, and of stricture of the colon. Mr. C. J. A. Woodside (Belfast) showed a case of hemiplegia with aphasia of central origin following head injury, a case of acute intestinal obstruction due to two separate co-existing lesions with recovery after six days' duration, and a gun-shot wound of the abdomen with perforation of small intestine and peritonitis, which terminated in recovery.

## YORKSHIRE BRANCH: WAKEFIELD, PONTEFRAC, AND CASTLEFORD DIVISION.

The annual meeting of the Wakefield, Pontefract, and Castleford Division was held at the Stratford Arms Hotel, Wakefield, on May 10th, when Dr. T. Gibson was in the chair.

The following officers were elected for the ensuing year:

Chairman, Dr. H. Scholefield. Vice-Chairman, Dr. J. R. Kaye. Honorary Secretary and Treasurer, Dr. N. S. Twist. Representative in the Representative Body, Dr. R. B. Radcliffe. Deputy Representatives in the Representative Body, Drs. T. E. Lister and G. B. Hillman.

The annual report of the Executive Committee was read by the Secretary and adopted.

The Annual Report of Council was considered. Several points of interest were discussed, and it was resolved that the representative be instructed to vote in favour of the Council's recommendations concerning the Manchester Unity of Oddfellows' juveniles.

In the absence of Dr. Manknell, owing to illness, his paper on the British Medical Association and the general practitioner was read by the Chairman. A vote of thanks was passed to the writer of the paper, and the honorary secretary was instructed to express the regret of the Division to Dr. Manknell upon his indisposition, and to wish him a speedy recovery.

In the subsequent discussion Drs. Hillman, Reynolds, Downie, Walker, Twist, Lyle, and Kaye took part.

NOTICES OF MOTION BY DIVISIONS FOR THE  
ANNUAL REPRESENTATIVE MEETING,  
CARDIFF, 1928.*Remuneration of Non-professional Medical Teachers,  
Laboratory and Research Workers.*

By HENDON: That the recommendation contained in para. 80 of the Annual Report of Council be amended to read as follows:

That the scale of salaries relative to non-professional medical teachers, laboratory and research workers, should not apply to those academic appointments in universities and medical schools which are of a temporary character and where the duties attached to the posts are in direct connexion with the advancement of the practitioner's knowledge and experience in the particular branch of work which he proposes to cultivate.

*Assistant Medical Officers to Mental Hospitals.*

By PERTH: That Recommendation C contained in para. 93 of the Annual Report of Council be amended to read as follows:

That those assistant medical officers to mental hospitals who had held the position of house-surgeon or house-physician for one year or who had held a hospital appointment for one year should receive an additional £50 per annum.

By PERTH: That the Representative Body is of opinion that subpara. (iii) of the last paragraph of para. 93 of the Annual Report of Council should be amended by the substitution, in the fifth line, of the words "recently admitted" for the word "acute."

*Paying Centres for Infant Hygiene.*

By PERTH: That (with reference to Recommendation A contained in para. 95 of the Annual Report of Council) in the opinion of the Representative Body it is undesirable that paying centres for infant hygiene be established.

*Protection of Medical Practitioner signing a Certificate under  
the Lunacy Act, 1890.*

By BOURNEMOUTH: That (with reference to the recommendation contained in para. 115 of the Annual Report of Council)—in regard to Section 330 of the Lunacy Act, 1890—(a) the onus of proof of want of reasonable care and want of good faith should be on the plaintiff; (b) unless the plaintiff can satisfy the judge that he is able to prove in a court of law the want of reasonable care and good faith, the case should not proceed to trial; and (c) the judge should be able to call in expert opinion on the point of reasonable care in respect of medical certificates if he himself is in any doubt.

By BOURNEMOUTH: That (with reference to the recommendation contained in para. 115 of the Annual Report of Council) if, under Sections 13 and 16 of the Lunacy Act, 1890, a magistrate make an order to one or two medical men as the case may be (two medical men under Section 13 and one under Section 16) to examine a person believed to be of unsound mind, it should be considered that the magistrate should be solely responsible as an instrument of the law and the doctors should have the status of a witness and enjoy the immunities of a witness.

*Method of Voting at Elections in Representative Meetings.*

By BOURNEMOUTH: That the method of voting at the elections in the Annual Representative Meetings should be by the simple majority vote, and not, as at present, by means of the single transferable vote.

By E. R. FOTHERGILL (Brighton): That Standing Orders 39, 42 (iv), 45 (vii), 46 (vi), 47 (iii), and 48 (iii) be amended by deletion of all reference to the single transferable vote as mode of election, and the substitution of the simple majority vote.

# British Medical Association.

## NINETY-SIXTH ANNUAL MEETING, CARDIFF, JULY, 1928.

Patron: HIS MAJESTY THE KING.

President: SIR ROBERT W. PHILIP, M.D., LL.D., F.R.C.P.Ed., Consulting Physician, Royal Infirmary, Edinburgh.

President-Elect: SIR EWEN J. MACLEAN, M.D., F.R.C.P., Professor of Obstetrics, Welsh National School of Medicine.

Chairman of Representative Body: C. O. HAWTHORNE, M.D., F.R.C.P.

Chairman of Council: H. B. BRACKENBURY, M.R.C.S., L.R.C.P.

4.30 p.m.—Annual Conference of Consulting Pathologists Group.  
6.30 p.m.—Secretaries' Dinner.  
8.30 p.m.—Reception by Lord Mayor and City Council, City Hall.  
10.0 p.m.—Dance.

##### THURSDAY, JULY 26TH.

Breakfast, League Breakfast, Central, Charles Street.

and Childs Cups.

10.0 a.m.—Excursions for Ladies.  
3.30 p.m.—Garden Party in the Grounds of Cardiff Castle, by invitation of the Marquis and Marchioness of Bute.  
7.15 p.m.—Annual Dinner of the Association, City Hall.  
10.0 p.m.—Dance.

##### FRIDAY, JULY 27TH.

8.30 a.m.—Medical Missionary Breakfast.  
9.0 a.m.—Registration Office, Exhibition, and Pathological

1  
1  
2.0 p.m.—Contest competition for Treasurer's Cup.  
7.30 p.m.—Popular Lecture by Sir Berkeley Moynihan.  
8.30 p.m.—Reception by National Museum of Wales.  
10.0 p.m.—Dance given by South Wales and Monmouthshire Branch.

##### SATURDAY, JULY 28TH.

Excursions.

## PATHOLOGICAL MUSEUM.

THE committee appointed to organize the Pathological Museum in connexion with the Annual Meeting of the British Medical Association at Cardiff next July proposes to arrange the material under the following heads: (1) Exhibits bearing on discussions and papers in the various Sections. (2) Specimens and illustrations relating to any recent research work. (3) Instruments concerned in clinical diagnosis and pathological investigation. (4) Individual specimens of special interest or a series illustrating some special subject. (5) Exhibits of general interest. The committee appeals for the co-operation of the profession in making the museum a success. It will be easy of access, being situated in the same building in which the Sections will meet; it is hoped to make arrangements for exhibitors to demonstrate their specimens. Every care will be taken of the exhibits, and the contents of the museum will be insured. The honorary secretaries (Dr. J. B. Duguid and Dr. J. Mills, Department of Pathology and Bacteriology, Welsh National School of Medicine, The Parade, Cardiff) ask intending exhibitors to notify them as soon as possible.

## REDUCED RAILWAY FARES.

Reduced fares will be granted to persons travelling to attend the Annual Meeting. The railway companies in Great Britain (except the Metropolitan, Metropolitan District, and London Electric Railway Companies) have agreed to issue return tickets to passengers travelling to Cardiff in this connexion at the ordinary single fare and one-third, fractions of 3d. to be reckoned as 3d., and the minimum adult fare to be 1s. A voucher of the usual type must be surrendered when the ticket is bought; these vouchers, signed by the Financial Secretary of the Association, will be obtainable from him in due course on application.

## HOTEL ACCOMMODATION.

THE following is a list of the hotels in Cardiff and district, with a statement of the charges for bed and breakfast:

	s.	d.
Angel Hotel ... ..	14	0
Royal Hotel ... ..	14	0
Queen's Hotel ... ..	14	0
Grand Hotel ... ..	10	0
Barry's Hotel ... ..	9	6
Alexandra Hotel ... ..	8	0
Railway Hotel ... ..	8	6
Great Western Hotel ... ..	8	6
Central Hotel ... ..	7	6
Sandringham Hotel ... ..	7	6
Esplanade Hotel, Penarth ... ..	*18	0
Washington Hotel, Penarth ... ..	10	0
King's Head Hotel, Newport ... ..	10	0
Westgate Hotel, Newport ... ..	10	0

\*This charge includes dinner.

Penarth is only about five miles from Cardiff and so within easy reach. Newport (Mon.) is about twelve miles from Cardiff, and the new arterial road connecting the two towns will be in an advanced stage of completion by July. There is also an excellent train service, the journey taking about twenty minutes. Besides the above accommodation a number of boarding-houses, hostels, and private apartments are available. A large amount of such accommodation has been secured, and members who intend going to Cardiff are requested to write without delay to the Hotels and Lodgings Secretary. It would be a great favour also if those members who have made private arrangements to stay with friends would inform the Hotels Secretary of the name and address of the friends with whom they are staying, as it is the wish of the Local Executive that, as far as possible, invitations to certain functions should be sent to those who are entertaining members of the Association. When writing for accommodation it is most important that members state clearly (a) whether they will be accompanied by a lady, (b) whether they are coming by car, and (c) the exact dates of intended arrival in and departure from Cardiff. This last point is very important, as it is found that many members omit this when writing, and so cause much unnecessary correspondence. The Honorary Secretary of the Hotels and Lodgings Committee, to whom all communications should be addressed, is Dr. Abel Evans, 36, Newport Road, Cardiff.

## ANNUAL DINNER OF THE ASSOCIATION.

THE annual dinner of the Association will be held in the Assembly Rooms, the City Hall, Cardiff, on Thursday, July 26th, at 7.15 p.m. The dinner will be open to ladies and lay guests, and it is likely that the number present will be large. The price of the ticket is 15s. (exclusive of wines), and, as the tickets will bear the number of a table and a seat, it is particularly requested that those who wish to sit together or make up parties will arrange this before application, as it will be impossible to alter seating at a later date. Application, accompanied by remittance, should be made to the Honorary Secretary of the Dinner and Dance Committee, Dr. T. R. Rees, 1, Walker Road, Splott, Cardiff.

## WELSH CONCERT AT THE CARDIFF MEETING.

AN important musical event in connexion with the Cardiff Meeting will be a Welsh concert, which will be held in the New Theatre, Cardiff, on the evening of Monday, July 23rd. The Downis Male Choir will sing, and the other artists taking part include Mr. Tudor Davies, Miss Megnn Foster, and Miss Gwendolyn Mason the well-known harpist. The love of the Welsh people for music is well known, and this concert will demonstrate to the visitors that in Wales they can not only appreciate good music, but can also produce musicians of the first order. It is likely that the concert will be broadcast.

## ARRANGEMENTS FOR SPORTS.

WHILE appropriate attention has been paid to the scientific and medico-political sides of the Annual Meeting in Cardiff, visitors will find that extensive arrangements have been made for social entertainment and for sports.

## Golf.

IN the realm of golf the competition for the Ulster and Childo Cups will be held on Thursday, July 26th, on the links of the Southerndown Golf Club. Southerndown is about an hour's run from Cardiff, and arrangements have been made for the competitors to go down in two parties, one starting at 9 a.m., and the other at 1 p.m.

The conditions of play are the same as in previous years, and intending entrants should send their names, with the necessary particulars, to Dr. Garfield Evans, 127, Cathedral Road, Cardiff.

The final stage of the Treasurer's Cup competition will be played on the Royal Porthcawl course on Friday, July 27th. Play will commence at 2 p.m., and the party will leave Cardiff at 1 p.m.

Practically all the golf clubs in the vicinity of Cardiff have thrown their courses open to visiting members for the week of the Meeting, and a full list of these will be published in the *Handbook of the Meeting*.

The Notts Ladies Challenge Cup, which was presented by Mrs. Owen Taylor of Nottingham in 1926, will be played for on the morning of Wednesday, July 25th, on the course of the Royal Porthcawl Club. As Porthcawl is about an hour's run from Cardiff, charabancs will leave the Ladies' Club at 9 o'clock that morning.

The conditions of play are the same as in previous years, and competitors should send their full names, addresses, and L.G.U. handicaps to Mrs. Garfield Evans, 127, Cathedral Road, Cardiff, as soon as possible, and not later than July 16th.

The competition is open to lady members, wives of members, and daughters of members; other lady relatives accompanying members may be allowed to compete under special conditions.

## Lawn Tennis.

TWO tennis tournaments have been arranged, both on the courts of the Cardiff Lawn Tennis Club. On Thursday, July 26th, a ladies' doubles American tournament will be held at 10 a.m., and at the same hour on the following day a mixed doubles tournament will be held. Intending competitors for either event are asked to send their names to Mrs. Garfield Evans of 127, Cathedral Road, Cardiff, without delay, so that the necessary arrangements can be made. Besides the Cardiff Club practically all the lawn tennis clubs in Cardiff and district have offered visiting

members and their ladies the hospitality of their courts, and a full list of these will be found in the *Handbook* of the meeting.

#### Bowls.

Arrangements have also been made for members to indulge in the games of bowls, and a number of excellent bowling greens in Cardiff and the surrounding area have been thrown open to visiting members. It is hoped that advantage will be taken of this, and, if a sufficient number apply, a bowling competition will be arranged between a local green and a B.M.A. team. Any members intending to take part in this competition are asked to communicate with Dr. R. C. Robertson, Struan, Llanbradach, near Cardiff.

#### IRISH MEDICAL SCHOOLS' AND GRADUATES' ASSOCIATION.

THE annual luncheon of the Irish Medical Schools' and Graduates' Association will be held at the Royal Hotel, Cardiff, on Wednesday, July 25th, at 1 o'clock sharp. The President-Elect of the British Medical Association, Sir Ewen Maclean, will be the guest of the association. Tickets for the luncheon, price 4s. 6d. each, exclusive of wines, may be obtained from the honorary secretary for the provinces, Dr. Falkland L. Cary, 67, King's Road, Harrogate. Members of the association are particularly requested this year to obtain their tickets well in advance, owing to the difficulty of catering for an unknown number of guests.

## CONTRIBUTORY SCHEMES FOR HOSPITAL BENEFIT.

### CONFERENCE OF MEDICAL REPRESENTATIVES OF VOLUNTARY HOSPITALS.

A CONFERENCE, summoned by the British Medical Association, and composed of representatives of the medical staffs of voluntary hospitals from all parts of the kingdom, was held in the Great Hall of the British Medical Association House, Tavistock Square, London, on June 6th, to discuss contributory schemes for hospital benefit (defined in the hospital policy of the British Medical Association as schemes "to which contributions are made for which there is to be a stated or implied return"). A memorandum setting out the basis of discussion had been circulated, and attention was drawn to certain principles which the Association regards as fundamental and to be insisted upon before any contributory scheme is launched—namely:

(a) That only persons below a definite income limit should be entitled to join a contributory scheme for hospital benefit.

(b) That (except in emergency) a contributor to a scheme should only be admitted to hospital upon the recommendation of the attending practitioner.

(c) That recognition should be made of the services of the medical staff.

The chair was taken by Dr. H. B. BRACKENBURY (Chairman of Council of the Association), who was supported by Dr. C. O. Hawthorne (Chairman of the Representative Body), Mr. N. Bishop Harman (Treasurer), and Mr. W. McAdam Eccles (Chairman of the Hospitals Committee). The attendance was very large, representatives being present from some forty hospitals in London and about one hundred and fifty hospitals elsewhere in Great Britain and Ireland. Every type of voluntary hospital was included—general, special, and cottage hospital. Representatives came from as far north as Dundee, as far north-west as Belfast, and as far south-west as Plymouth. The proceedings lasted little more than two hours, but during that time a very useful discussion took place.

The CHAIRMAN, in opening, said that the subject before this large and representative conference was not the whole position of voluntary hospitals, their means of support, and their methods of management, nor the proposed grouping of hospitals and co-ordination of hospital services. The subject was the relationship of hospital staffs to contributory schemes, and if speakers kept to that subject they would have plenty to occupy their time. The preponderating support of the voluntary hospitals had gradually shifted from charitable subscriptions and donations to other contributions not charitable in nature, but having the character of insurance payments made with a view to an explicit or implied return. The problem was to resolve what action should be taken by hospital staffs in this new situation—for the prevention of the exploitation of their services and also for the preservation of their interests as private practitioners. One of the great difficulties was that the persons responsible for contributory schemes were very often not the same persons as those responsible for the management of the hospitals; when there were defects in the construction or working of the schemes there was apt to be a tossing of the responsibility from one body to another. Clearly, then, the

subject was a complicated one. No doubt all those present were conscious of the peculiar circumstances or difficulties of their own hospitals or areas, but he begged them in conferring not to think too closely of their own localities, and to remember that some sacrifice of one's particular point of view might be necessary in arriving at any common policy.

#### *The History of Hospital Policy.*

Mr. BISHOP HARMAN (Treasurer of the British Medical Association) presented two documents which had been circulated, one the memorandum on contributory schemes, already mentioned, and the other the British Medical Association's pamphlet entitled "Policy Affecting Hospitals," the latter being a compendium of the policy of the Association which had been arrived at in the course of the last seven or eight years. This policy, he said, was based upon resolutions passed by the Representative Body. Such resolutions had to be published two months before the meeting, and, further, in order to become the policy of the Association, they had to be agreed to by a majority of at least two-thirds. Ordinarily a matter of policy came from some Division which sent up its recommendation, but in this matter of hospital policy the Hospitals Committee of the Association set itself to the task as far back as 1921. A memorandum was then drafted, submitted to the Council, debated very keenly again and again, ultimately reaching the Divisions, and then the Representative Meeting. This had now grown in subsequent years to the pamphlet which was in the hands of those present. The policy embodied therein dealt with many points, such as the co-ordination of all sorts of hospitals, the development of voluntary hospitals, the position of statutory hospitals, and so forth, but only one section of it—that relating to contributory schemes—concerned the present meeting. The Association (Mr. Bishop Harman continued) had never failed to recognize that it had a duty to the whole profession, and in this matter the Council determined not only to consult the members of the Association, but the staffs of hospitals generally. During the last six or seven years there had been a series of such conferences. The first was held during the Annual Meeting at Cambridge in 1920, and was presided over by Sir Cuthbert Wallace, when the principal item discussed was the relation of hospitals to State-supported patients. At that conference one well-known consultant complained bitterly of the inarticulateness of hospital staffs. The next conference was in London in December, 1920, under the chairmanship of Sir James Galloway, when the principal business was the preparation of evidence to be laid by the Association before the Cave Committee. The conference which followed was among London hospital staffs on matters affecting London particularly. Another conference was held in 1922, when the statement of policy was considered clause by clause. During the next year the Labour party brought out its hospital policy, and in 1924 there was an interesting two-day conference between the Labour party and the Association's representatives; after that debate the attitude of the Labour party was considerably modified. The Labour spokesmen had come prepared to accept State hospitals and nothing else, and as a result of that conference they went away recognizing that the voluntary hospitals had a place in the nation.

*An Ideal Contributory Scheme in London.*

Mr. W. McADAM ECCLES (Chairman of the Hospitals Committee of the British Medical Association) said that the Treasurer of the British Medical Association had given the history of the evolution of the criteria for what might be described as an ideal contributory scheme for hospital benefit. It was not always the case that ideals could be made to fructify, and, further, it was obvious that an ideal might be possible in one environment and impossible in another. Such an ideal scheme (Mr. Eccles continued) had been inaugurated and carried out in London. London was huge, populous, and difficult to co-ordinate. The economic stress following the war led to the preparation of a scheme for hospital benefit whereby those persons who were wage-earners could voluntarily and cheerfully contribute towards their maintenance and treatment while at hospital, whether as in-patients or out-patients. This was the scheme of the Hospital Saving Association, and it fulfilled all the criteria laid down by the British Medical Association, although it was found to be somewhat difficult to get them actually carried out. As to income limit, it was definitely laid down that the contributor's income must be within hospital income limits, as follows: single man or woman, £4 per week; married, without dependent children, £5 per week; married, with dependent children, £6 per week. These were comparable to the British Medical Association figures, which set out the yearly income. A definite income limit was essential in the interests of the medical staff and the private practitioner. As to the requirement that admission to hospital must be, except in emergency, on the recommendation of the attending practitioner, the principle was over and over again propounded in the literature relating to the scheme and in meetings convened by the Hospital Saving Association, and its desirability was gradually taking hold of both patient and practitioner. There were "snags," however, one of which arose out of the wish of some patients to visit the hospital on their own initiative, presenting the "green voucher." The Hospital Saving Association could not absolutely prevent this, but the hospital itself could do so by making it a rule that all green vouchers must be accompanied by a doctor's recommendation. Upon this rule the medical staff should insist. Another "snag" was discovered when the attending practitioner was found not to be desirous of giving a recommendation to his patient for hospital consultation or treatment or both. This refusal might be quite legitimate in some cases, but on the other hand there were instances in which the recommendation was withheld perhaps without due reason. Such action was apt to lead to trouble, and it was difficult to see how it could be overcome, except, perhaps, by change of doctor. The third principle, that recognition should be made of the services of the medical staff out of the money received by the hospital from a contributory scheme, was perhaps the most debatable. Mr. McAdam Eccles read the paragraphs of the hospital policy of the British Medical Association bearing upon this matter:

Payments made... be for work done based on... time to time between the... making full allowance for provision of hospital accommodation, maintenance, and payment of medical staff.

When the Board of Management of a voluntary hospital enters into a financial arrangement... under a contributory scheme or otherwise for the reception of patients, such arrangement should be taken to cover the cost of maintenance and medical treatment, and a percentage of all such receipts should be passed into a fund which is at the disposal of the honorary medical staff of that hospital.

The contract made was for hospital benefit as a whole, consequently the payment under any financial arrangement was for treatment as well as for accommodation and maintenance. When interrogated, nine out of ten subscribers to the scheme would express their belief that they had contributed towards treatment, and it was only fair that this legitimate belief should not be betrayed. It was, however, the medical staff who should impress upon the lay authorities of the hospital that a percentage of the money thus received should pass into a medical staff fund. It was hardly the function of the administrators of the contributory scheme to do so. Where medical staffs had done this, their request had not been resented, and where money had been passed over the amount received had been used by the staffs for very good purposes. Often it had gone to supplement the scientific equipment of the hospital—for example, to install an extra cardiographic apparatus or addi-

tional x-ray tubes. No amount which might possibly be received could be called adequate for all the service rendered, but in these days it was essential that there should be some recognition of the work done by the medical profession on behalf of those who believed they had actually paid for the same. ("Hear, hear.") Many objections had in the past been raised against a medical staff fund, but these were gradually disappearing, and an increasing number of medical staffs saw the wisdom of such a fund. (Applause.)

*The Position on Merseyside.*

Dr. J. C. MATTHEWS (Liverpool) mentioned some of the difficulties which had arisen in applying the Association's three principles in his own area. The main difference between the provinces and London in respect to contributory schemes was that in the provinces the contributions were organized through the various works or employers, and in most cases the employers added a percentage. It was hoped ultimately to include in the scheme the hospitals in the neighbouring townships of Merseyside; the population affected would be about one million. The problem in Liverpool had been under discussion for several years. A scheme was finally launched which was satisfactory to the staffs, and operations were started in July of last year. For several reasons not concerning the medical profession the scheme was undergoing revision at the present time. In this revision all the points of professional interest also had come under discussion again, and had more or less been re-argued. The staffs of the voluntary hospitals of Liverpool alone comprised about one hundred individuals; they had formed themselves into a Hospital Staffs Association, and it was this body, with the very active and willing co-operation of the local Division of the British Medical Association, which had so far carried on the negotiations. As for the three main points of the scheme, the first two (income limit and practitioner's recommendation) were agreed; on the third (recognition of services of medical staff) there were still some differences of opinion. The lay authorities of the hospitals in Liverpool, however, had begun to realize the justice of the claim. The following paragraph appeared in the original scheme, and had been included in the recent report of the Reversion Committee:

That the hospitals be asked to give favourable consideration to the request of the doctors for the allocation by the hospital to the hospital staff funds of an agreed percentage of grants received from the council.

One step further was being taken: the Hospital Staffs Association hoped to arrange for a conference with nominated representatives of the lay committees of the hospitals. There was some uneasiness on the part of hospital treasurers with regard to the success of the contributory scheme, and the negotiations were not yet completed. He felt, however, that their lay friends in Liverpool were largely in agreement with the request that the services which the hospital staffs rendered to contributors should cease to be gratuitous. In consequence of the scheme a number of employers had ceased to give their former subscriptions, and for the moment hospital incomes appeared to be going down. The rapid growth of the scheme, however, rendered it very probable that there would be ample funds available for hospital needs, and that then the request of the staffs for recognition would be brought forward with a prospect of its favourable reception.

*The Cottage Hospital.*

Dr. C. LAMPOUGH (Gosport) spoke of the question as it affected a cottage hospital—namely, the Gosport War Memorial hospital, with 26 beds. On the staff of this hospital all the practices in Gosport were represented, and there were three honorary visiting surgeons from Portsmouth. The three fundamental principles set out by the Association had been adopted: contributions were obtained by a voluntary levy on each employee's weekly wage; a committee elected annually by the workers themselves organized and managed the scheme; persons whose income from all sources was less than £250 per annum were eligible, unless they were single persons or persons without dependants, in which case their income must not exceed £200 per annum. The rate of contribution was one penny per week per £1 of wage, but nothing had been contributed by the employers. Of the total sum contributed to the fund, 70 per cent. was paid to the hospital for maintenance of patients; 20 per cent. to the medical staff fund, and 10 per cent. was used

for various purposes, including an allocation to the local district nursing society, contributions to the Portsmouth hospitals in respect of patients there, and administrative expenses of the scheme, these last amounting only to 1.25 per cent. of the total. The contributory scheme brought to the hospital three times as much as was received from charitable subscribers and donors. The scheme had worked very satisfactorily, but there was a tendency for representatives of the scheme to try to increase their numerical strength in the management of the hospital, and owing to the large proportion of revenue received from this source the Hospital Management Committee rather tended to sympathize with this attempt. The hospital was immensely popular in Gosport, and the annual income was invariably larger than the expenditure. Nothing was paid to the medical staff fund from receipts other than the contributory scheme. (Applause.)

#### GENERAL DISCUSSION.

After these three opening statements from different points of view, general discussion was invited.

Mr. H. S. SOUTTAR (London Hospital) said that those of them who had studied contributory schemes would realize that these were going to have a revolutionary influence on the future of the hospitals and of the medical profession. They were not a small thing which was going to come in to-day and make some trivial difference to the subscriptions. They were going to alter entirely the whole basis of the hospital clientele and treatment. The subject was a complicated one, and he desired to confine himself entirely to one small aspect, placing before the conference some considerations as to the purpose for which the contribution was made. The answer to such a question given by the committee of the hospital would most likely be entirely different from the answer given by the patient. The committee would assert that the contribution was to meet the cost of maintaining the patient in hospital, his food and clothing, and so forth, and that it had nothing to do with medical treatment. The patient, on the other hand, would say that he gave his contribution in order that when he wanted medical treatment he should be able to get it. The fact that he had to be fed and maintained, he would claim, was a mere incident; the important thing from his point of view was the treatment. ("Hear, hear.") The patient did not want to be maintained for some weeks in a hospital bed; what he wanted was to get rid of his hernia, or whatever the trouble might be. This question was extremely important at the present moment. Upon the decision of the hospital staffs would depend the whole future of the contributory schemes. If hospital staffs allowed the idea to take root that all the contributory scheme had to do was to provide for the "keep" of the patient in hospital, that idea would be established as a permanent principle. It was perfectly obvious that an ordinary working man could not stand the expenditure of a big operation or of a long medical illness, but if in times of health and prosperity he subscribed a very small amount he would be able to cover the whole of that expense. Actuarially, if a workman paid sixpence a week it would cover handsomely the probable cost of any hospital maintenance and treatment that he might require. If he did not pay for his treatment, what was, in fact, the economic position of the hospital staff? A man came into hospital, say, for a hernia, for which he was relieved, and he paid the hospital £8. Who had earned that £8? The point which the speaker wished to make was that as long as the staffs were not paid it was the staffs who were paying for the hospital. But he did not think his own chairman would like him to send in a little note at the end of his operating session and say, "Kindly add thirty guineas as my donation to-day to the hospital fund"! He asked again, For what was this contribution paid by the prospective patient? If it was recognized that the patient really was paying for the treatment he received, if the patient was greeted in hospital as a man who was paying his way, instead of it being derogatory for recognition to be made of the services of the medical staff, it added to the dignity of the profession and of the patient as well. (Applause.) He begged that it might be recognized that in the contributory scheme the patient paid for his treatment. Why should anyone be shy or squeamish about admitting it? (Loud applause.)

Mr. EDWARD DEANESLY (Wolverhampton and Staffordshire Hospital) said that the staff of his hospital were in entire agreement with the principles enunciated for contributory schemes. He was sure that these schemes were going to

revolutionize the finances and position of the whole profession. All hospitals were looking round for fresh sources of income, and the only source in sight, apart from grants from the Government, was these contributory payments. At present the employers did not pull their weight; they did not make, as employers, the contributions to hospitals which they ought to make. It was forgotten by them that it was impossible to carry on industry in any town in the kingdom without a well-equipped hospital; they did not always realize that they were getting something for nothing. One great difficulty which was already confronting Wolverhampton was the overlapping of contributory schemes. It was not acceptable to have a London agent coming down and suggesting that the people should make their contributions to London hospitals rather than to their own. In the Wolverhampton area the local hospital was well supported, largely because of the good management of the Hospital Saturday Fund. But Birmingham had launched a scheme which practically promised hospital treatment to all contributors, although such a promise could not be fulfilled on account of lack of accommodation. Unless something was done to remedy the overlapping of areas a scheme would be met by insuperable difficulties, and it was no easy matter in a large area to bring about co-ordination.

Dr. W. COLLIER (Radcliffe Infirmary and County Hospital, Oxford) said that in connexion with the County Hospital one of the earliest of the contributory schemes was started and had been extremely successful; it had prevented the hospital from falling into a third-rate position. In 1913 the working income was under £10,000 a year; at the present time it was £42,000. A large part of the income came from agricultural labourers. At the same time those concerned had been out to protect the interests of the general practitioner, and, as far as possible, the consultant. The first two principles in the policy of the British Medical Association had been accepted, the third principle—recognition of the services of the staff—not yet. If the staff went to the committee to-morrow and said, "You must pay up a definite amount from the contributory scheme to the medical staff," he thought the contributory scheme would be at once destroyed. But as the result of the present discussion he thought that the medical staffs in the county hospitals would take the question up much more seriously than they had done hitherto. With regard to Mr. Souttar's point about sixpence a week from the worker, this would be impossible of application to the agricultural labourer, who was earning only 30s. a week.

Mr. R. ST. LEGER BROCKMAN (Sheffield Royal Infirmary) said that from the point of view of finance as seen by the lay boards the Sheffield scheme had been a huge success. But thirty, forty, or fifty small tradesmen who could afford to run their own motor cars were now joining the scheme on the basis of paying £1 a year. The unfortunate thing was that Sheffield refused the income limit at the beginning. The scheme had been running for some years, and all these people were in. If, now, the staffs insisted on the income limit, these people would have to come out of the scheme, and the staff would be accused of wrecking tactics. The position was unfortunate; there was a lack of hospital beds, and waiting lists tended to lengthen, while continual pressure was put on the staffs through various large firms who claimed to be paying so much to the scheme—in Sheffield the employers gave one-third of what the men gave—and wanted a *quid pro quo*.

Dr. A. J. BALLANTYNE (Glasgow Eye Infirmary) declared that in Glasgow there was no such thing as a contributory scheme. There the hospital system was as close to voluntarism as anything could be. Large contributions certainly were made by the workers, but no conditions were laid down as to privileges or specific services in return. Although, so far as was known, there was no contributory scheme in Glasgow at present, it was felt that such a scheme might be brought forward at any time; it was largely a question of facility in securing funds. In considering the principles laid down in the Association's memorandum it was felt in Glasgow that there was a certain lack. It might easily happen that in some hospitals the governors would be approached by lay bodies, such as representatives of the workers, with a view to devising some contributory schemes without the staffs being consulted; indeed, it was stated that the medical staffs of the hospitals concerned in many instances had not been consulted in the setting up of the scheme. Something should be laid down by the Association as a principle to be observed—namely, that staffs

in these cases must be consulted. A contributory scheme implied a contract between the contributor and the hospital with regard to services, and the members of the medical and surgical staffs would be parties to such a contract, and should be consulted with regard to the scheme. If a scheme were devised without consultation with the medical staff the staff would be greatly strengthened in its opposition could it point to something which had been definitely laid down by the Association in this connexion. He wished to move a resolution on the subject.

The CHAIRMAN thought it would be inadvisable in a meeting of that character to pass any definite resolutions, though he would not rule out some general proposition which would receive practically unanimous assent. It was quite in order, however, to mention and speak to a resolution which the speaker would like to have had brought forward.

Dr. BALLANTYNE said that he would, in deference to the chairman, refrain from proposing any resolution, but he asked members of staffs to be wary lest a contributory scheme be brought forward without the staff being taken into consultation.

Dr. CLIFFORD ELLINGSWORTH, though representing the West London Hospital, spoke on behalf of the London Panel Committee, on which he represented the non-insurance practitioners north of the Thames. The Panel Committee had asked him to express its agreement with the principles laid down by the Association in regard to contributory schemes, but to state that certain hospitals did not confine the benefit to hospital treatment. In their out-patient departments they invaded the province of the general practitioner. The Panel Committee was of opinion that general practitioner treatment should not be provided by the hospitals under the contributory schemes. Many voluntary hospitals, the speaker continued, were run by lay secretaries, whose ambition was to get as many green vouchers as possible without considering the work thrown on the hospital staff or the injustice done to the general practitioners. Mr. Sontar had mentioned that patients thought they were paying for their treatment. The speaker declared that they did not in any way pay for their treatment; was it recognized that at the present time the voluntary hospitals had become the x-ray centres for the whole of their district, including the service of insured patients, who, with the green voucher, demanded and received x-ray treatment at the hospital? The same was true of drugs for which there was specific provision under the national health insurance system without reference to the hospital.

Dr. R. WHITTINGTON (Hove Hospital) asked how far visits and consultations at the patient's house should be included in contributory schemes. Any contributory scheme which was going to be of great use to the patient must include in some cases consultations at the patient's house or at the consultant's house. At the hospital there were a number of patients who came up for consultations, and one would like to know how far the contributory schemes ought to cover the cost of consultations in those cases that could not come up to the hospitals. Such cases ought to be covered by any adequate contributory scheme. When the scheme in his own area was started such service was included, and an adequate fee of three guineas was apportioned to the consultant who saw the patient either at his own house or at the patient's house. This provision had recently, without any consultation with the medical profession, been cut out of the scheme, and it seemed to him that it must of necessity be so cut out if contributions to the scheme were to be kept as low as they were under most of the schemes now in existence. If a contributory scheme was to be of use it should be on an actuarial basis so that the contributions were adequate to the benefits.

Sir RICHARD LUCE, M.P. (member of the Hospitals Committee), said that this question had had a long history. The question arose soon after the war, when it began to be recognized by a very large number of members of hospital staffs that the time had come for some recognition of the work done at hospitals. But practically nothing had been done in the way of obtaining that recognition which was then said to be necessary. It was difficult to see the reason for this long delay in coming to a definite issue. All members of staffs felt a certain diffidence in approaching the boards of hospitals to ask money for themselves, and probably that had been one of the obstacles to progress; they liked also the freedom given to them as voluntary workers. But there was no doubt that the time

had come when it was necessary that the vast amount of work done in hospitals should receive some remuneration, especially in the case of the younger members of the staffs. If this was not done now it was difficult to see when it would be done. Suppose the State took over the hospitals; what could the staffs say when the State was their master if they had been willing to work for nothing under the present system? It was essential to be prepared for such an event by some sort of payment. There were already State hospitals and municipal hospitals the staffs of which were getting a certain amount of remuneration. As time went on these hospitals might grow and come into competition with the voluntary hospitals, and if the staffs of one kind of hospital were paid and the staffs of another were not the result might be to the detriment of the voluntary hospitals. It seemed to be the duty of the conference to make a determined effort to arrive at some practical conclusion on this aspect of the question. (Applause.)

Dr. C. HERBERT HALL (Watford and District Peace Memorial Hospital) asked how it had come about that the British Medical Association scheme had not been accepted more widely. One great reason was that it had not received the support of the consultant staffs of the big London hospitals. Again, this was primarily a question for the staffs of hospitals. It was they who must bring forward the case before their committees, and it was particularly the seniors who should do it, but it was not being done. His colleague Dr. Francis Smith and himself at Watford were just approaching the end of their time at the hospital, and they had been sent forward by the staff to advocate before the committee the British Medical Association scheme in its entirety. The committee had listened to them because it recognized that they had no axe to grind for themselves. One mistake made at Watford was that the British Medical Association scheme was not taken in its entirety at first; it was very desirable to have a scheme logical from beginning to end. The Watford experience was that when it came to debating with the committee as to the hospital staff fund the Labour element on the committee proved to be the strongest supporters of the staff, recognizing that the doctor should receive his share. The total amount of new money coming to his hospital as a result of the scheme was £4,000 a year at least, and the medical staff had been offered a fixed sum of £350, which they had turned down. He thought that sufficient emphasis had not been laid at headquarters on the desirability of having a percentage arrangement. He and his colleagues believed that the scheme at Watford would presently be earning for the hospital from £8,000 to £10,000 a year, and the staff should receive an increased amount accordingly, as it would do on a percentage basis. He urged support for the full British Medical Association policy, with the principle of a percentage.

Dr. CRANSTON WALKER (Birmingham and Midland Hospital for Skin and Urinary Diseases) begged the conference to remember that the sick man's claim to service was fundamentally based on his sickness, not on his membership of a particular scheme or guild or clique, nor on his position in society, nor on his means. He also mentioned the nurses, who, in voluntary hospitals, were to a large extent, like the medical staff, donors of their services. They were not paid fairly or properly, and he would suggest that with funds available it was the duty of the medical staff to see that some proportion of such funds went to the nurses.

Mr. A. J. WALTON (London Hospital), referring to the remarks just made by Dr. Hall, and his rebuke to the consultants of the London hospitals for not giving full support to the scheme, said that he thought the rebuke justified, and he would like to throw a little light on the position. Of the three fundamental propositions set out, the second one (admission only on the recommendation of the attending practitioner) had been universally accepted. His own hospital had become much more than formerly a consultative centre, and most of the patients admitted were admitted more or less at the request of himself and his colleagues. The difficulty was that they had no adequate means of determining what was the patient's income. It happened that certain patients paid sums up to £5 per week for their maintenance. On one or two occasions, on mentioning to the lay committee that there were such patients, he had been told, "Yes, but the cases were admitted at your own request." The staff had no means of discovering the patient's economic circumstances. With regard to the third principle (recognition of the services of the medical

committee might also refer cases of this nature to the Insurance Committee for investigation by the Medical Service Subcommittee. In the particular case which led to the conference the Ministry had informed the Insurance Committee that it was in order for the subcommittee to investigate the matter, and therefore the Panel Committee decided to take no further action at present.

#### Definition of a Splint.

It was reported that the Ministry of Health, in reply to a request by the committee, had furnished a definition of a splint: "... the department take the view broadly that splints are appliances intended to secure immobility of bones or parts of bones in relation to one another, in the treatment of fractures, dislocations, diseased or injured bony surfaces or joints, and ruptured muscles or tendons." The Ministry had previously excluded a spinal jacket from being defined as a splint, and the committee requested to be informed in what way a spinal jacket was contrary to the description of the splint laid down in the letter.

#### DANGEROUS DRUGS: WITHDRAWAL OF AUTHORIZATION.

The Home Secretary gives notice that he has withdrawn from Frederick Denis Parbury, M.R.C.S., L.R.C.P., of Elsham Road, Kensington, the authorizations granted by the Regulations made under the Dangerous Drugs Act, 1920, to duly qualified medical practitioners to be in possession of and to supply raw opium and the drugs to which Part III of the Act applies, and has also directed that the exception in Regulation 4 of the Dangerous Drugs Regulations, 1921, which permits dangerous drugs to be supplied on a prescription given by a duly qualified medical practitioner, shall not apply in respect of prescriptions given by Dr. F. Parbury. Any person supplying Dr. Parbury with raw opium or any of the drugs to which Part III of the Dangerous Drugs Act, 1920, applies, and any person supplying the drugs on a prescription signed by him, will be committing an offence against the Acts.

### Naval and Military Appointments.

#### ROYAL NAVAL MEDICAL SERVICE.

Surgeon Commander R. J. G. Parnell, seniority in present rank ante-dated to May 5th, 1921.

Surgeon Commander D. P. H. Pearson is placed on the retired list.

Surgeon Commanders C. Ross to the *President* for post-graduate course; W. F. Beattie to the *Victory* for R.M. Barracks, Portsmouth.

Surgeon Lieutenant Commander J. F. Ainley to the *Egmont* for hospital ship *Moine*, and as ophthalmic specialist from date of joining.

Surgeon Lieutenants R. R. Baker to the *Vindictive*; W. D. M. Sim to the *Pembroke* for R.M. Infirmary, Chatham, temporary (amended appointments); T. L. Cleave to the *Collipe*; P. C. H. Bamford to the *Tamar*.

Messrs. F. Dolan, S. J. Savage, and R. E. P. Cohen have entered as Surgeon Lieutenants for short service, and appointed to the *Victory* for R.N. Hospital, Haslar, for course of instruction.

#### ROYAL NAVAL VOLUNTEER RESERVE.

Surgeon Lieutenant W. J. Payne to be Surgeon Lieutenant Commander. Surgeon Lieutenants W. Winstanley to the *Seikirk* to complete fourteen days' training; J. L. Cox to the *Seikirk* for eighteen days' training, appointment to *Empire of India* cancelled; J. B. Oldham to the *Victory* for R.N. Hospital, Haslar, for training; R. Eskine-Gray to the *Pembroke* for R.N. Hospital, Chatham.

#### ROYAL ARMY MEDICAL CORPS.

The notification in the *London Gazette* of November 28th, 1917, regarding temporary Captain Robert B. Martin, M.C., is cancelled.

Temporary Lieutenant Robert B. Martin, M.C., relinquishes his commission, November 14th, 1917.

Henry McNeill to be temporary Lieutenant.

Lieutenant on probation J. G. Weston resigns his commission.

#### REGULAR ARMY RESERVE OF OFFICERS.

##### ROYAL ARMY MEDICAL CORPS.

Lieut.-Colonel M. P. Corkery, O.B.E., having attained the age limit of liability to recall, ceases to belong to the Reserve of Officers.

#### ROYAL AIR FORCE MEDICAL SERVICE.

Wing Commanders F. N. B. Smartt to No. 1 Air Defence Group Headquarters, W. A. S. Duck, O.B.E., to Wessex Bombing Area Headquarters, Andover.

Flight Lieutenant (honorary Squadron Leader) H. C. Perkins relinquishes his temporary commission on completion of service, and is permitted to retain the honorary rank of Squadron Leader.

Flight Lieutenant H. B. Troup is promoted to the rank of Squadron Leader.

Flight Lieutenants J. K. R. Landells to R.A.F. Depot, Uxbridge; G. E. Church to R.A.F. General Hospital, Iraq.

Flying Officers J. Hill to R.A.F. Combined Hospital, Iraq; L. Freemantle to Station Headquarters, Hinaidi.

#### INDIAN MEDICAL SERVICE.

Lieutenant-Colonels to be Colonels: J. W. D. Megaw, C.I.E., vice Colonel C. R. Bakke, K.I.F.; retired; Brevet Colonel W. D. A. Keys, C.I.E., vice Colonel H. M. Cradock, C.I.C., O.B.E., retired.

Lieut.-Colonel G. D. Franklin, O.B.E., an Agency Surgeon, is posted as Civil Surgeon, Ajmer, and Chief Medical Officer in Rajputana.

Lieut.-Colonel J. R. J. Tyrrell, an Agency Surgeon, is posted as Chief Medical Officer in Central India, and Agency Surgeon, Indore.

Major W. E. R. Dimond, Officiating Assistant Director of Public Health, North-West Frontier Province, is confirmed.

Major H. B. Gibson, whose retirement was notified in the *London Gazette* of December 31st, 1926, is granted the rank of Lieutenant-Colonel. The services of Major G. B. Hanna are placed permanently at the disposal of the Government of Bengal, with effect from October 24th, 1927, for employment in the Jail Department.

Captains to be Majors: J. E. Ainsley, David Clyde, and R. A. Leembruggen.

Lieutenant T. A. Malone to be Captain.

Lieutenant J. H. Clapp has resigned his commission.

#### TERRITORIAL ARMY.

##### ROYAL ARMY MEDICAL CORPS.

Captain J. K. Rennie, M.C. (late R.A.M.C., T.A.) to be Captain with precedence as from October 26th, 1926.

#### TERRITORIAL ARMY RESERVE OF OFFICERS.

##### ROYAL ARMY MEDICAL CORPS.

Major J. H. Donnell, having attained the age limit, relinquishes his commission and retains his rank.

Captain C. F. Hardy, M.C., having attained the age limit, relinquishes his commission and retains his rank.

General Hospitals.—Captain W. Seymour, having attained the age limit, relinquishes his commission, and retains his rank.

Hygiene Companies.—Captain D. Smith, having attained the age limit, relinquishes his commission and retains his rank.

#### COLONIAL MEDICAL SERVICES.

Dr. N. P. Jewell appointed Resident Surgical Officer, Nairobi Hospital, Kenya. Dr. H. B. Owen, Medical Tutor, Makerere College, promoted Medical Superintendent, Mulago, and Principal of the Medical School. Dr. G. F. Allen appointed Bacteriologist, Institute for Medical Research, Federated Malay States. Dr. W. L. Paterson appointed Medical Officer, Kenya. Drs. N. J. Williams and R. E. Barrett appointed Assistant Bacteriologist and Medical Officer, Uganda, respectively. Dr. J. J. Mitchell, Medical Officer, appointed Medical Officer, Hoima, Uganda. Miss C. N. Twining appointed Lady Medical Officer, Kenya. Captain M. Clayton-Mitchell appointed Resident Surgeon, Colonial Hospital, Grenada, Windward Islands. Miss J. M. M. Aitken appointed Lady Medical Officer, Gold Coast. Drs. H. V. R. Miller and J. H. Pottinger appointed Medical Officers of Health, and A. Reid appointed Medical Officer, Gold Coast respectively. Dr. D. Whitbourne appointed Lady Medical Officer (for one year only) to Lagos Town Council, Nigeria. Dr. R. N. Hunter appointed Medical Officer of Health, Nairobi Municipal Area, etc., Kenya.

#### VACANCIES.

BIRNLEY: BECKETT HOSPITAL AND DISPENSARY.—House-Physician (male). Salary £140 per annum.

DUNSTABLE: NORTH DEVON INFIRMARY. House-Surgeon. (male). Salary at the rate of £150 per annum.

BIRMINGHAM GENERAL HOSPITAL.—Assistant Surgeon. Honorarium £50 per annum.

BOMBAY: COMA AND ALEEF'S HOSPITAL FOR WOMEN AND CHILDREN.—Medical Officer in Charge (lady). Remuneration Rs.800-50-1,000 per mensem for officer of Asiatic domicile, and Rs.600-50-800, plus £20 per mensem on overseas pay for officer of non-Asiatic domicile.

BRIGHTON: NEW SUSSEX HOSPITAL FOR WOMEN AND CHILDREN.—(1) Honorary Assistant Ophthalmic Surgeon. (2) Honorary Clinical Assistants for out-patients.

BRISTOL: EYE HOSPITAL.—Honorary Rhinologist.

BURY INFIRMARY.—Senior House-Surgeon (male). Salary at the rate of £200 per annum.

CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, Victoria Park, E.2.—(1) Radiologist; honorarium 150 guineas per annum.

EAST SUSSEX COUNTY COUNCIL.—Coroner for the Lewes District. Salary £750 per annum.

EAST SUSSEX COUNTY MENTAL HOSPITAL, Hellingly.—Junior Assistant Medical Officer. Salary £350 per annum, rising to £400.

ERITH UNION DISTRICT COUNCIL.—Medical Officer of Health. Salary £800 per annum.

GLOUCESTERSHIRE ROYAL INFIRMARY AND EYE INSTITUTION.—Resident Surgical Officer (male). Salary £175 per annum.

HARPENDEN GENERAL AND NORTH-WEST LONDON HOSPITAL, Harpenden Hill, N.W.3.—Casualty Surgical Officer at the Out-patient Department, Bayham Street. Salary at the rate of £100 per annum.

HAVE HOSPITAL.—Resident Medical Officer (male, unmarried). Salary £150 per annum.

HULL ROYAL INFIRMARY.—(1) Assistant House-Surgeon (male). (2) Casualty House-Surgeon. Salary £150 and £130 per annum respectively.

IPSWICH: EAST SUFFOLK AND IPSWICH HOSPITAL.—Two House-Surgeons (males). Salary at the rate of £100 per annum each.

LEDS JEWELL HAZEL-MOSER HOSPITAL.—Resident Medical Officer. Salary £50 per annum.

LONDON CORPORATION.—Medical Officer of Health for the Port of London. Salary £1,500 per annum, rising to £2,000.

MANCHESTER: ANCHORS HOSPITAL.—House-Surgeon (Orthopaedic). Salary at the rate of £100 per annum.

MANCHESTER EDUCATION COMMITTEE.—Assistant School Medical Officer. Salary £600 per annum, rising to £750.

MANFIELD AND DISTRICT HOSPITAL.—Assistant House-Surgeon (male). Salary at the rate of £150 per annum.

MARGHERIT STREET HOSPITAL FOR CONSUMPTION, 26, Margaret Street, W.1.—Honorary Assistant Physician.

MILLER GENERAL HOSPITAL, Greenwich Road, S.E.10.—(1) House-Physician. (2) House-Surgeon. Males. Salary at the rate of £125 per annum each.

NEWCASTLE-UPON-TYNE: ROYAL VICTORIA INFIRMARY.—(1) Medical Registrars. Salary £250 per annum each. (2) Honorary Assistant to the Ophthalmic Department.

NEWARK HOSPITAL AND DISPENSARY.—Resident House-Surgeon (male). Salary at the rate of £150 per annum.

POPPIE HOSPITAL FOR ACCIDENTS, E.—Senior Resident Officer. Salary £200 per annum, plus fees £75 per annum as Anaesthetist to Dental Clinic for L.C.C. School Children.

## British Medical Association.

### PROCEEDINGS OF COUNCIL.

Wednesday, June 13th, 1928.

A MEETING of the Council of the British Medical Association was held at the Association's House in Tavistock Square, London, on Wednesday, June 13th. Dr. H. B. BRACKENBURY took the chair at 10 a.m. Those present were:

Sir Robert Philip (President), Dr. C. O. Hawthorne (Chairman of Representative Body), Mr. Bishop Harman (Treasurer), Mr. R. G. Hogarth (Past President), Sir Ewen Maclean (President-Elect), Dr. A. Lyndon (Deputy Chairman of Representative Body), Sir Robert Bolam (Immediate Past Chairman of Council), Dr. J. Barcroft Anderson, Dr. J. Armstrong, Dr. F. J. Baidon, Major-General Sir Alfred Blenkinsop, Dr. J. W. Bone, Dr. H. C. Bristowe, Dr. G. F. Buchan, Dr. H. G. Dain, Dr. C. E. Douglas, Mrs. T. P. Dunhill, Mr. W. McAdam Eccles, Dr. T. Fraser, Dr. F. W. Goodbody, Rear-Admiral J. Falconer Hall (ret.), Dr. R. Wallace Henry, Dr. G. B. Hillman, Dr. J. Hudson, Dr. I. W. Johnson, Dr. E. K. Le Fleming, Dr. R. W. Leslie, Dr. E. Lewys-Lloyd, Dr. J. Livingstone Loudon, Sir Richard Luce, M.P., Dr. J. G. McCutcheon, Dr. S. Morton Mackenzie, Dr. O. Marriott, Dr. J. C. Matthews, Dr. G. W. Miller, Dr. Christine Murrell, Lieut.-Colonel F. O'Kincaly, Dr. W. Paterson, Dr. R. C. Peacocke, Dr. J. R. Prytherch, Dr. F. Radcliffe, Dr. E. H. Snell, Mr. H. S. Souttar, Dr. E. A. Starling, Dr. Lockhart E. W. Stephens, Dr. John Stevens, Lieut.-Colonel Ashton Street, Dr. W. E. Thomas, Dr. G. Clark Trotter, Mr. E. B. Turner, Sir Jenner Verrall, Dr. J. E. Walker, Mr. A. M. Webber, Sir William de Courcey Wheeler.

Apologies for absence were received from Dr. D. E. Finlay, Dr. P. J. Gomez, Dr. R. Langdon-Down, Mr. A. W. Nuthall, Mr. J. Patrick, Group-Captain N. J. Roche, Dr. D. Walshe, and Dr. W. E. A. Worley.

The Chairman referred at the outset to the death of Dr. J. A. Macdonald. The Council, he said, over which Dr. Macdonald had presided for a longer period than any other Chairman, had peculiar opportunities of appreciating his qualities and the great work which he had done for the profession over many years, though it was a work which, the speaker feared, had not been appreciated by the rank and file of the profession as it should have been. The Council had also to deplore the loss of another valued member, Dr. A. Manknell, and of two former members, Dr. G. E. Shuttleworth and Dr. W. Snodgrass.

The members stood for a few moments in a silent tribute.

The Chairman was authorized to convey to those members of the Association whose names figured in the recent Honours List the Council's congratulations.

A communication was received from the Canadian Medical Association intimating that in connexion with the Annual Meeting to be held at Winnipeg in 1930 it desired to nominate Dr. Harley Smith as President of the British Medical Association for 1930-31. It was agreed to recommend this nomination to the Representative Body.

Certain tentative arrangements for the Annual Meeting in 1930 were discussed. The suggested date for the opening was August 26th, and a programme was sketched following more or less closely that of the Annual Meeting in this country. It was stated that the Representative Meeting would be held that year in London. Some discussion took place on the probable expense of travel to Canada, and the chairman said that at the earliest moment—probably at the Cardiff Meeting—an announcement on this subject would be made. In the meantime the greater the number of members who intimated the probability of their attendance the more favourable were the terms likely to be.

A report was received from Sir Robert Philip on the Harvey Tercentenary Celebrations, which he attended as President of the Association. He wrote that the profession owed a debt of gratitude especially to Sir John Rose Bradford for the reverent dignity with which, as President of the Royal College of Physicians of London, he conceived and managed the numerous functions.

The Council approved the action of its chairman in having nominated Dr. J. W. Bone as representative of the Association on the Departmental Committee on the Midwives Acts; Mr. R. G. Hogarth and Sir Thomas Horder as the Association's delegates to the forthcoming International Congress on Cancer in London; and Dr. F. G. Thomson, Dr. W. E. A. Worley, and Dr. J. D. R. Monro as practitioners who might suitably be co-opted on the medical committee of the proposed London Clinic for Rheumatic Diseases promoted by the British Red Cross Society.

Sir Robert Philip, the President, was appointed to represent the Association at the annual conference of the National Association for the Prevention of Tuberculosis, to be held in London in October, and Dr. W. Paterson at the National Conference on Maternity and Child Welfare in July. Sir Humphry Rolleston's appointment as representative of the Association on the advisory committee of the Pharmaceutical Society concerned with the control of therapeutic substances was renewed, as was that of Mr. Russell Coombe on the court of governors of the University College of the South-West of England.

It was reported that the Brighton Division executive committee had complained that the section dealing with the International Union of Medical Organizations in the Annual Report of Council was too meagre in respect to the details it furnished to permit of the committee advising the Division as to what action it should take, if any, on the Council's decision. (The Council decided, as stated in the Supplement

of April 21st, p. 126, not to join this international medical movement.) After some discussion it was agreed to send to the Brighton Division, and to any Division making similar inquiries, any information in the Council's possession with regard to the subject, and to refer them to the reports of the discussions in the Council on this subject, as printed in the *Supplement*, but the Council did not see its way to publish in the *Supplementary Report* the lengthy memorandum by the Medical Secretary which was before the Council.

#### *The Medical Service in India.*

Dr. Goodbody, chairman of the Naval and Military Committee, brought forward a report on the reorganization of the medical services in India, which had been the subject of a communiqué issued by the India Office. From this communiqué it appeared to be contemplated that the proportion of European to Indian officers in the Indian Medical Service would greatly diminish, though the committee had been assured that for the present at all events there would be a ratio of approximately one Indian to two Europeans in the service taken as a whole. Dr. Goodbody pointed out that one of the chief inducements to candidates entering the Indian Medical Service in the past was the prospect of civil employment. Under the new arrangements the prospects of such employment were materially diminished. An officer might enter the service believing that he would have opportunities for civil employment, but yet be retained during the whole of his period of service on the military side. It was true that after a period of six or twelve years' service an officer might retire on a gratuity of £1,000 or £2,500 respectively, provided he gave notice of such intention twelve months in advance. The committee believed that this safeguard would be still more valuable if the officer were informed at the end of his fourth or tenth year of service what his prospects of civil employment were; he would then be able to judge whether or not it was in his interests to remain in the service. The committee did not consider that the new proposals would attract an adequate number of European medical men to the service, and put forward a recommendation that the Secretary of State for India be informed that the new proposals did not seem likely to have this effect so long as the posts of chief administrative medical officers of local governments were not scheduled on the list of appointments reserved for I.M.S. officers, and so long as definite information as to the prospects of civil employment as just stated were not afforded to the officers. Dr. Goodbody added that some later information made him feel that had such information been before the committee at the time of its meeting the recommendation would have been still stronger. The important fact brought out was that the heads of the medical services of the provincial governments need not be members of the Indian Medical Service at all. The largest hospital for Europeans in India, at Calcutta, which was solely concerned with Europeans, could be officered under this arrangement by non-European members of the I.M.S.

Lieut.-Colonel O'Kinealy said that since the meeting of the Naval and Military Committee he had had the opportunity of seeing and hearing from several brother officers of the service, and the general conviction was that the civil side of the service under these new conditions was practically moribund. In the first place, it was said that on the civil side 178 posts would be provided in the provinces, and that 112 of that number must be held by British officers. The memorandum went on to say: "The medical requirements of European members of the Superior Civil Services are based on data which will change from year to year as the proportion of European to Indian officers gradually diminishes and will be subject, therefore, to periodical revision"—in other words, the reserved appointments for European officers of the Indian Medical Service would gradually pass away. Of these appointments reserved for officers of the I.M.S. a number were definitely reserved for British officers; others were open to Indian officers equally with British. In the Government of India, the headquarters of the Government of the country, the Department of Education, Health, and Lands, under which the medical service worked, had thirty appointments reserved to officers of the Indian Medical Service, and out of this number twenty-five might be held by Indian officers, these twenty-five including the director-generalship of the Indian Medical Service, the deputy director-generalship, and the two assistantships of the director-general. In the Foreign and Political Department, which looked after the interests

of all the native States (that is, the States ruled by Indian princes), it was somewhat significant that out of twenty-nine posts reserved for officers of the I.M.S. only three were open to Indian officers. With regard to the local governments a very important matter had to be pointed out. At the present moment the presidencies of Madras, Bombay, and Bengal each had a surgeon-general, and each of the provinces, such as the United Provinces, Punjab, Bihar and Orissa, and the Central Provinces, had an officer of the I.M.S. as inspector-general of the civil hospitals. Under this schedule not one of these appointments was even mentioned as to be occupied by an officer of the I.M.S. He asked the Council to think of the feelings of the men in the Indian Medical Service at the present time, who went in with the prospect of rising to administrative grade. It was not too much to say that this was a death-warrant to their hopes, and he trusted that the Council would put up a strong protest. Take Calcutta: there the Medical College Hospital and the Gynaecological Hospital each had a resident surgeon and the former a resident physician. These three appointments were all held by officers of the I.M.S. at the present moment, but they were excluded from this list. In the Presidency General Hospital—the European general hospital at Calcutta—there were two resident surgeons, both of them European officers of the I.M.S., and these appointments again were excluded from this list. The surgeon-superintendent of the European general hospital in Calcutta might be an Indian officer of the I.M.S. There were three professorships at the Medical College, Calcutta, which were reserved for British officers of the I.M.S. who were "specially qualified" as physician, surgeon, and gynaecologist. But when it came to deciding what was meant by "specially qualified" might it not be urged that men applying were not "specially qualified" because they had not been resident in these particular hospitals? Colonel O'Kinealy said in making these remarks he was not intending to cast any reflection on the Indian members of the service, many of whom were men of the highest professional standing, but he was now dealing with the possibilities of the service attracting a sufficient number of the right kind of European officer. He moved as an amendment to the committee's recommendation:

That the Secretary of State for India be informed (1) that the Association has carefully considered the new proposals for the reorganization of the medical services in India and notes that the prime object of the proposals is to maintain a war reserve of military medical officers and to provide European medical attendance for European officers of the Superior Civil Services and their families; (2) that the Association is convinced that the new proposals will not attract an adequate number of European medical men to the Indian Medical Service so long as (a) the chief administrative medical officers of local governments are not specifically included in the list of appointments of officers of the Indian Medical Service, and so long as (b) the prospect of employment on the civil side, which is the chief inducement to enter the I.M.S., is as indefinite as it is at present.

Sir Alfred Blenkinsop seconded the amendment, and associated himself with all that Colonel O'Kinealy had said.

The amendment was accepted by Dr. Goodbody, and agreed to unanimously.

Colonel O'Kinealy said, in reply to a question by Sir Jenner Verrall, that at the present moment European medical officers were practically non-procurable from the military side for the civil side. The military side declared that it had not got its full strength, and therefore he did not think it could be blamed for not sparing officers, but the result was that British officers were not being obtained as they were required for the civil side.

#### *Scale of Salaries for Public Health Appointments.*

Sir Robert Bolam, as chairman of the conference between representatives of the Association and of the Society of Medical Officers of Health, brought forward a report with recommendations, which had been postponed from the previous meeting of Council in order that the public health representatives might be present. He said that the conference met on March 28th, and considered some suggestions from the representatives of the society with a view to the modification of the scale of salaries for whole-time public health appointments. Before dealing with these, however, it would be well to have regard to the position in Scotland, where the conference recommended that the working arrangement agreed to for one year as from June last with regard to the application of the scale to Scottish public health appointments, and approved by the Representative Body in 1927, should be extended for a further period of

one year on the understanding that, if by the end of that period experience showed that these arrangements had not brought about that measure of success in the application of the scale to Scotland which would justify continuing the arrangement, the advisability of reverting to the original scale should be considered.

Dr. G. W. Miller, chairman of the Scottish Committee, moved that instead of an extension for one year it should be for five years. He said that after the Council authorized the Scottish Committee to negotiate with the Scottish Board of Health and the local authorities the committee succeeded in converting the Board to acquiescence. A circular letter was drawn up by the Board for issue to all health and education authorities in Scotland, but when the Board found that the modified scale was authorized for one year only it did not issue the letter and would not issue it. Nevertheless, the Board had advised the payment of salaries at scale rates where the authorities had consulted it during the past year. He wished to impress upon the Council the importance of this modified scale for Scotland. The opinion both among medical officers of health and general practitioners was unanimously in its favour. Only the other day the medical officer of health in his own town expressed to him the hope that the modified scale would be adopted, as otherwise all would be confusion. The Scottish people had a pretty good hump of common sense, and knew that, the financial conditions in Scotland being what they were, it was of no use asking the local authorities, who were seeking to economize in every possible direction, to give what they regarded as extravagant salaries to their medical officers. To limit the extension to one year was to send them into the fight with their hands tied.

Dr. Douglas seconded the amendment. He asked whether it could be of any use to put forward a scheme for one year only. One year's experience was not sufficient for any body of men to estimate the working of such a matter as this. The Board of Health was willing, if the period were made five years instead of one, to back them up. The Board was shortly going out of existence; its power in a year's time would be nil, and the matter of public health would be dealt with by the Secretary for Scotland. Was it not common sense to have this matter dealt with by the Board of Health while it still had power, and get it established for a term of years? In reply to Dr. Buchan, who had asked whether the terms of the letter of the Board of Health alluded to were satisfactory, Dr. Douglas said that the terms were such as to make it clearly understood that the grant would be awarded in the case of any authority which adopted the scale. Dr. Buchan still wanted to know whether the grant would be withheld in the case of any authority which did not.

Dr. McCutcheon said that the members and officials of the present Board would do their best to get the scale adopted in Scotland, but not if it was to be only for one year.

The Scottish amendment extending to five years the working arrangement agreed to was carried, and the Scottish Committee was instructed to obtain full details of all appointments made under the arrangements, and of all in which the salary was below that laid down in the modified scale.

The Council then returned to the question of the proposals made on behalf of the Society of Medical Officers of Health with regard to certain points for an improvement in the scale which might be put up to local authorities.

Sir Robert Bolam reminded the Council of the history of this subject. He said that of late years the situation in respect to the existing scale in England and Wales had greatly improved, so that at the present time a very large number of appointments were on that scale. What was proposed in the conference from the side of the representatives of the society was that the Association should issue a suitable letter to all local authorities asking them to give favourable consideration to the following points in connexion with new and existing appointments:

- (a) Reasonable increments (25 per cent. on the minimum in eight years).
- (b) Suitable grading for senior medical officers (£750-£1,100) on certain lines duly set out and based on population.
- (c) Suitable scale for deputy medical officers of health (60 per cent. of salary of medical officers of health).
- (d) Application of scale to existing officers.
- (e) Suitable recognition of long service (after ten years' service a further 25 per cent. on the minimum in five years).

Sir Robert Bolam said that the last suggestion would mean

that if an officer was appointed at a basic salary of £800 this would rise in eight years to £1,000, and after two further years the long service period would be reached, and then under the scale proposed there would be further emolument, so that in fifteen years from the time of appointment the basic salary would be raised from £800 to £1,200. At the conference in question he took what he thought to be the proper course for the chairman of such a body; a conference was rather different from a committee, and in a conference such as this, consisting of representatives of two bodies, matters could not usefully be put to the vote and decided by a majority. He had felt, therefore, that the best course was to bring the proposals to the Council and let it decide. He was bound to say that the Ministry of Health was not favourable to the proposals suggested, and would consider itself compelled to make quite clear to the local authorities that it had no part or lot in them, though it could take no objection to propaganda work on their behalf. Sir Robert Bolam added that he considered the matter was not helped by the practice of the Society of Medical Officers of Health in publishing in its journal particulars of these matters before they had been considered by the Council of the British Medical Association, which in the end must take, or refuse to take, action. The question for the Council was whether it was a politic thing at the present time to send this forward to the local authorities, not as a policy which was going to the Representative Body, but as the opinion of the Council. If the Council set its name as the executive of the Association to a letter of this kind it must be held to approve the reasonableness of the proposals.

Dr. Johnson pointed out that any proposals of this kind would cause other officials of local authorities to appeal for similar concessions.

Dr. Buchan said that the Society of Medical Officers of Health was not asking for any revision of the scale, except in two instances—namely, a suitable grading for senior medical officers on the range of salaries between £750 and £1,100, and that the deputy medical officer of health should receive a salary equal to 60 per cent. of that of his chief. At the present time senior medical officers were all in the grade of £750 to £1,100, and as a result of experience it had been found that no matter how large the area in which the senior medical officer worked his salary was much nearer the lower end of the scale than the upper. It was felt, therefore, that a considerable grading of that salary should be undertaken. Many local authorities required guidance in these matters. With regard to the other items all that was being asked for was a rise in salary for certain officers in certain localities. He did not think it was anything very exceptional to ask for a rise of salary after a number of years' service. Now that the minimum scale had in fact been decided upon it had caused local authorities to say, "Oh, the officer is getting the scale salary. What more does he want?" The Public Health Service representatives were not asking the British Medical Association to depart in any way from the terms of agreement which had been reached with the Ministry of Health, nor that these suggestions should be made the policy of the Association, but merely that they should be indicated as a guide to the authorities. What they were asked for was chiefly certain increases in salary, and it was thought better that these increases should be asked for collectively than individually by members in the different areas. No attempt was to be made to enforce the points, but only to appeal to the sense of justice among local authorities. Save in Scotland, the minimum scale operated in something like 90 per cent. of cases, so that it could not be said that there was anything ridiculous about the £600 minimum for assistant medical officers, and all that was asked for was that steps should be taken to get reasonable increments in accordance with these various suggestions.

The Chairman (Dr. Brackenbury) said that the Council had two questions to consider: first, whether these propositions were reasonable in themselves, and secondly, whether it was a wise thing at present to write round officially to the local authorities commending these propositions. With regard to this second question, he was bound to say that in his opinion it was not. Although the success in applying the scale had been quite gratifying—he was speaking of England and Wales—yet there was, he believed, at the present moment more irritation at the scale among local authorities than there had ever been since it came into existence. The officers of the Ministry of Health, who were in the best position to know, stated that that was so. They were having more trouble with—more

protests from—local authorities on all hands with regard to their support of the scale than they had had at any time during the past three years or so for which they had given it their official support. The Association of Municipal Corporations had indicated to a number of authorities that its support of the scale was not as wholehearted as it had sometimes been represented—not by the British Medical Association—and that all that it had said was that it was willing as an Association to have it sent out to local authorities with the statement that it was commended to them as a guide which was not unreasonable in influencing their independent action when making appointments. The County Councils Association never had approved the scale, in spite of modifications in the direction which it desired, and it was being asked at the moment to start on a very definite parliamentary campaign against recognition of the scale by the Ministry of Health in any way whatever. During the previous week he had gone down to the annual meeting at Bath of the Association of Education Authorities; he had gone, not as a representative of the British Medical Association, but of an education authority, and his reason for going was because there was on the agenda a resolution with regard to the salaries of medical officers, protesting against the Ministry of Health backing up the British Medical Association and the Society of Medical Officers of Health. This body was at first inclined to say that there should be no scale at all; it had had to modify that position, but it protested against the Ministry of Health in any way identifying itself with a scale, and, above all, withholding giants—as it appeared the Ministry had done in at least one case (Lindsey, Lincolnshire)—from the local authority because the authority proposed to make an appointment at a figure below the scale. In face of this more militant attitude of the local authorities and of the fact that the fight for the minimum scale might have to be renewed, was it an appropriate moment at which to issue a letter which local authorities might regard, not as a mere pinprick, but, having great respect for the powers of the British Medical Association, as another attempt on the part of the Association—somehow they always spoke of the Association and not of the Society of Medical Officers of Health—to impose its opinion upon them? With regard to the Association of Education Authorities, whose idea was that there should be no scale at all, but that each authority should be master in its own house, he thought he had succeeded the previous week in presenting the view that better men would be got into the service if the service under all the various authorities were regarded as one whole service, not as a number of independent services, so that a man or woman could start anywhere in a junior appointment with the hope of rising to the highest administrative national posts. He had told the meeting at Bath that so far as medical men were concerned they were satisfied with the very general application of the scale in England and Wales, but that if any reasonable modifications of detail were proposed the representatives of the medical profession would very carefully consider them, also that if it was desired to set up an arbitration committee, which had been proposed from the medical side from the first, composed of representatives of both sides, with a representative of the Ministry of Health in the chair, this would be acceptable. He thought that the majority of representatives of education authorities were agreeable to such a proposition, but there was a powerful section which affirmed that it had no desire to go into conference, and, while accepting the desirability of a scale, held that its character must be gone into *de novo*. As to the reasonableness of the propositions, take the one which asked for suitable grading of senior medical officers. This was reasonable enough in itself, but the view of the local authorities was that the present scale had the advantage of allowing a considerable latitude to individual authorities; the more that latitude was impaired the more difficult it would be to persuade local authorities to accept the scale. With regard to the application of the scale to existing officers he really did not think that if this were pressed it would result in any better position. When a request came from an area for help to raise the salary to a more suitable level, if the Division supported the request, the Association was ready to exert whatever pressure it could, and, in fact, nothing more could be done in the collective way unless all existing medical officers felt the matter so strongly that they would resign their appointments and seek reappointment under the scale. He had also grave doubts about the increments proposed.

Sir Jenner Verrall considered that certain aspects of the proposals might be regarded as putting a pistol at the head of the people concerned.

Sir Robert Bolam thought that regard ought to be paid to the effect which the inevitable letter from the Ministry of Health would have on the existing scale. The Ministry would send down a letter dissociating itself from these proposals, and he feared the effect which this might have on the solid position already achieved.

Dr. Buchan replied that when recently he and others from the conference interviewed the officials at the Ministry of Health it appeared that the Ministry was at first under the impression that these points were to be enforced on local authorities, in which case the Ministry said that it would have to make it clear that it had no part in them; but it was afterwards stated that the Ministry had no objection to propaganda in the hope of bettering the position of officers appointed previous to the operation of the scale or establishing suitable increments.

The recommendation that the Association ask local authorities to give favourable consideration to these various points in connexion with new and existing appointments was lost by a large majority. It appeared that only the two members of Council elected by the public health service members supported the recommendation.

It was agreed to recommend to the Representative Body that the scale of minimum commencing salaries be made applicable to whole-time appointments in Northern Ireland.

#### *Annual Conference of New Zealand Branch: Delegate's Report.*

Mr. Victor Bonney, who was the official delegate to the annual conference of the New Zealand Branch of the Association in February last, was introduced to the Council at this point, and gave some account of his visit. Before he addressed the Council a letter which had been sent to headquarters from Dr. Hugh Douglas, President of the New Zealand Branch, was read, acknowledging the very kind greetings conveyed by Mr. Victor Bonney, whose presence, said Dr. Douglas, had helped to cement the bond of affection already existing between the Branch and the parent body. The sacrifice which Mr. Bonney and others had made in leaving their work to visit this distant part of the globe was fully appreciated, but the reflection that they had performed some very worthy service must be a compensation. Another letter expressing similar sentiments was received from the President of the Victorian Branch, which Mr. Bonney had also visited.

Mr. Bonney presented to the Association a gift from the New Zealand Branch in the form of an inkstand made of silver, greenstone, and New Zealand woods. He said that the inkstand was sent by the Branch as a token of its loyalty and affection to the parent body. He was charged to tell them that nowhere in the Dominions was there a body of men more loyal to the Association or more anxious to keep in touch with the old country. The inkstand was of purely New Zealand material. The top of it was made of New Zealand greenstone from the west coast of the South Island, the top of the plinth was of the magnificent kauri pine so characteristic of New Zealand, and other parts were of the honeysuckle tree and other woods. An old Latin quotation was inscribed on the plinth: "*Coelum non animus mutant qui trans mare currunt.*"

Continuing, Mr. Bonney described his tour through Australasia. He started at Hamilton in the North Island, about seventy miles south of Auckland, where the meeting opened; then went to Rotorua, where the second half of the meeting was held. After visiting Lake Taupo he went on to Napier, where he addressed a meeting of the Association, and then crossed to the South Island, and at Christchurch, a very flourishing and beautiful city, again addressed the local members. He lectured and operated also at Dunedin, a university town reminiscent of Edinburgh, and Queenstown, saw something of the lakes and the wonderful scenery of Mount Cook, then returned for three days to Wellington, on the North Island, visiting also Wanganui and New Plymouth, and finally getting to Auckland at the end of five weeks. During that time he had the opportunity of meeting the greater number of medical men in New Zealand. He lectured or addressed meetings at all these places, and operated at most of them. In every place he found the most extraordinary loyalty and the desire to be one with the old country.

Leaving New Zealand, he went to Sydney, and from there to Canberra, the new federal capital, where he was present at the inaugural meeting of the College of Surgeons of Australasia, and had the honour of being made an honorary Fellow. He next went to Brisbane, where he met the local members of the Association, meeting many more on returning to Sydney, after which he went to Hobart and Launceston, and then to Melbourne, where he spoke and operated at the four principal hospitals. He had thus acquired, for the time he was away, a very close insight into the conditions obtaining in Australasia. He had come back impressed with the need for maintaining closer relationships with the medical profession in the southern continent. While there was absolute loyalty to Britain and things British—indeed, it had made him ashamed to see the earnestness with which these people clung to the old country, even people who had never seen it, and who belonged to the third generation of Australasians—American influence and culture were very close, and there was some tendency for Australians to look to America for their literature and example. It was very important that frequent visits should be paid to these Dominions, and those who went out were really unofficial ambassadors. He also urged the need for establishing better facilities for post-graduate study whereby fruitful intercourse between Australasians and the mother country might be promoted.

The Chairman, amid the applause of the Council, expressed the pleasure with which the inkstand had been received, the latest of a number of prized possessions exhibiting the loyalty of the Branches overseas, and also thanked Mr. Bouney for the extraordinarily able and energetic manner in which he had carried out the mission entrusted to him. He assured him that his remarks would have the earnest consideration of the Council.

Another overseas matter mentioned was that Dr. Todd, honorary secretary of the New South Wales Branch, had forwarded a handsomely bound copy of the New South Wales medical roll of honour, compiled by Miss Dulcie Cohen, a member of the staff of the Association in Sydney, containing the date of appointment to service and honours of all members of the medical profession in New South Wales who had served overseas in the great war. The Council accepted the volume with thanks, and directed it to be placed in the Library of the Association.

#### *Medical Services in the Colonies and Dependencies.*

Dr. W. Paterson, chairman of the Dominions Committee, brought forward a report on several interesting matters. One was the position of the Windward Islands Medical Service. In December, 1927, the committee had reported that until the Association's suggestions with regard to salary, leave, and study leave had been adopted, or at any rate until some improvement had been made, it could not recommend the withdrawal of the "Important Notice" with regard to this service. Following this a letter was received from the secretary of the Grenada Branch pointing out that the revenue of the colony showed a substantial increase per head of a growing population, and that the annual deficit had been turned into a surplus. A letter was thereupon sent to the Secretary of State expressing the disappointment of the Association on finding that the estimates for 1928 showed no provision either for an improvement of the scale of salaries of the medical officers or for an increase in the medical establishment, and called attention to official statements which indicated that an improvement in the scale of medical salaries and an increase in establishment should receive attention at the earliest possible moment. The Colonial Office had forwarded a copy of this letter to the Governor of the Windward Islands. Another matter touched upon by Dr. Paterson was the indigenous systems of medicine in Ceylon, where, a year or two ago, the majority of a committee appointed by the Ceylon Government reported in favour of financial assistance for the training of those seeking to qualify themselves as practitioners of the indigenous systems of medicine and the investigation of the medicinal value of drugs used by those practising such systems. The Colonial Office had recently reported that the Legislative Council of Ceylon had made provision in its latest estimates for a grant for Ayurvedic study to the amount of Rs. 75,000 (about £5,000). The Secretary of State was not aware of the manner in which it was proposed to expend this sum.

#### *National Health Insurance (Amendment) Bill.*

Dr. Dain, chairman of the Insurance Acts Committee, brought forward the question of the National Health Insurance (Amendment) Bill, now before the House of Lords, which, he said, made several important alterations in the relations of the medical profession to the parties concerned in the administration of national health insurance, especially in regard to additional treatment benefits. The bill repealed a subsection in the 1924 Act which had been relied upon by the profession as securing that any additional medical benefits should not be administered by approved societies but through Insurance Committees. It appeared from the bill that approved societies would now be able to establish their own clinics for ophthalmic treatment and for any other kind of specialist treatment, and thus they would be in a position to select and control staffs and largely to determine the character of the treatment. It was true that the societies would be governed by regulations made by the Minister, which the Minister had promised should be submitted to the Association before approval, but the Insurance Acts Committee considered that the protection which the profession had enjoyed under the section of the old Act now proposed to be repealed was better than any protection under regulations. The Minister had declined to accept certain amendments which, in the committee's view, would have safeguarded the position. During the Committee stage the Minister of Health accepted a proposal for a further benefit—namely, "The payment of whole or any part of medical or surgical or specialist services." The Insurance Acts Committee pointed out to the Minister that the word "specialist" should not be used in any additional benefit clause, as this word did not appear to have been employed in the previous Acts, and was difficult of definition. The Minister agreed to a revised wording, and also to the inclusion of certain other words, which the committee had suggested should be inserted in an earlier clause, but which the Minister thought more suitable to this, so that the clause was put to, and accepted by, the standing committee in the following form: "The payment of the whole or part of the cost of medical or surgical treatment or advice by any registered medical practitioner not being treatment within the scope of any other additional benefit or of medical benefit under a special scheme approved by the Minister for the purpose."

The Council agreed at this point to take a reference in the report of the Hospitals Committee to this same subject.

Mr. McAdam Eccles, chairman of the Hospitals Committee, said that his committee had had under review only the question of how this bill for the increase of benefits under the Act concerned the staffs of hospitals. The committee was of opinion that the members of the staffs of voluntary hospitals should not take part in any additional treatment benefit under the Acts at a hospital or other charitable institution if its administration and control was to be wholly by approved societies, even though these should be governed by regulations made by the Minister of Health.

Dr. Hawthorne here moved what was in some sense an amendment to this part of the report of the Hospitals Committee:

That in the opinion of the Council it is essential, if the medical profession is to take part in the provision of additional treatment benefits under the National Health Insurance Acts, that these, as is the case with statutory medical benefit, shall be administered in such a fashion that the services of the medical practitioners who elect to give advice and treatment in connexion therewith shall not be under the direction and control of any approved society or societies; and that this position shall receive statutory recognition and definition.

He said that the discussion in the Hospitals Committee had necessarily to be confined to the position as affecting hospital staffs, but it was obvious that when additional benefits became established they might be given by consultants who were not members of hospital staffs, and thus the Hospitals Committee's expression of opinion covered only a part of the situation. He thought it was the general wish of the Hospitals Committee to have a more inclusive resolution. Another reason which led him to frame this proposal was that the conditions under which additional benefits were to be given would depend upon regulations by the Ministry, and naturally might vary with the Minister's political complexion and outlook. The only secure position would be to have such conditions defined in the Act itself. He added that just as the Association years ago fought for the protection of the practi-

tioner from interference by approved societies in connexion with ordinary medical benefit, so the Association should fight to-day to secure that when the consultants came under the Aet they also should be protected from similar interference.

Dr. Goodbody seconded. Mr. Eccles said that Dr. Hawthorne's proposal did express the feeling of the members of the Hospitals Committee, and therefore he supported it, though he was afraid the time was too far gone for the last clause to be effective.

Some discussion took place on the meaning of the word "control" in the resolution. Dr. Wallace Henry asked whether the appointment of, say, two representatives of an approved society on the board administering the benefit would constitute "control." Dr. Hawthorne replied that "control" signified any arrangement which allowed representatives of approved societies to be able to overmaster and direct the administration of any particular benefit. He consented to the omission of the last sentence in his resolution, having no wish to press anything which was doomed in advance to futility.

Dr. Le Fleming and Mr. Turner were against this dropping of the reference to statutory recognition, the latter declaring his "profound disrespect for legislation by regulation." He thought the Council should stick to its guns. The Chairman pointed out the difficulty, if any part in the administration were allowed to the approved society, of arriving at a form of words which would allow of so much voice as was safe without making its influence preponderant.

Dr. Buchan said that the form of "control" to be allowed to approved societies in additional medical benefits should obviously be the same as that exercised by them in the case of ordinary medical benefit. The Chairman said that the approved societies exercised no control whatever over ordinary benefit. It was true that in practice officials of approved societies were the representatives of insured persons on Insurance Committees, but the approved societies as such were not represented. There was more than one method whereby control might be secured. The competent body administering medical benefit might contain no representatives of approved societies at all, it might consist wholly of representatives of one or more societies, or it might consist of a miscellaneous group of persons interested, including a certain number of representatives of societies, and it would be possible to get preponderant control by the societies even though their representatives on the administrative body were not in an actual majority. But for practical purposes the rather vague word "control" was perhaps the best. It was not laid down that there must be no representation of approved societies on these bodies.

After further discussion it was agreed that the last clause of the resolution, calling for statutory recognition and definition, should not form part of the main resolution, but should be put subsequently, and Dr. Hawthorne also agreed to a suggestion that, instead of the words "under the direction and control of any approved society," the phrase should be "under the control of any approved society." In this form the resolution was adopted unanimously. The further proposition, "That in the opinion of the Council this position should receive statutory recognition and definition," was put as a rider, and also agreed to. The report of the Insurance Acts Committee was then approved.

Sir Robert Bolam raised the question of the interpretation and interrelation of certain of the clauses in the schedule of the new bill, wherein the additional benefits were set out, and after some conversation on these points he moved that the bill should be amended in respect to the clause in the schedule which ran: "Payments to approved charitable institutions in respect of any treatment of members required for the prevention or cure of disease, not being treatment within the scope of any other additional benefit or of medical benefit." His motion was that this should not be capable of adoption by an approved society without it being allowable at the same time to have payments to private practitioners for similar advice and treatment at places other than clinics or institutions.

This was agreed to unanimously in the hope that it would still be possible in the House of Lords to secure an amendment to this effect.

#### *Fees for Inspection of Vagrants.*

Dr. Hillman, acting-chairman of the Public Health Committee, said that a number of inquiries had been received as to the fees which the Association considered appropriate for

inspecting vagrants for small-pox. Previous to the meeting of the Public Health Committee, the Medical Secretary had advised inquirers that the Association had laid down no rate of remuneration for this service, but that if it was on a sessional basis a fee of £1 11s. 6d. per session of not more than two hours might be found suitable, or, if on a capitation basis, 1s. per head, with a maximum of one guinea per hour, and a minimum of 10s. 6d. per attendance. The Public Health Committee had expressed the opinion that suitable remuneration for this service would be 1s. per head, with a minimum of 10s. for any one visit.

Dr. Bone said that this service was now being carried out in practically every workhouse with a casual ward in this country. He gave one instance within his own knowledge. The examinations began on January 23rd, once daily at 7.30 p.m., until February 13th, when they were carried out twice daily, at 7.30 p.m. and 8 a.m. The morning examinations were discontinued on April 25th. During the whole period 14,439 examinations were carried out on 9,686 individuals by one doctor up to June 12th. Each session occupied about one and a half hours, so that 432 hours' service were given. At the rate suggested by the committee of 1s. per head the sum to be received by the doctor would be £721; at the sessional rate of £1 11s. 6d. the 288 sessions would mean £453. The sum which the guardians actually offered, up to June 30th, was £250, which the doctor was very pleased to accept, but the Ministry said that this must not be paid, and suggested instead £5 5s. per week as a maximum, which meant £120. What the Ministry offered was, of course, far too low, but the figures suggested by the committee seemed to be unduly high, and he suggested that this matter be referred back for further consideration, and that in the meantime the committee get in touch with the Poor Law Medical Officers' Association and with the men actually carrying out this work.

Dr. Buchan pointed out that this was an exceptional service; it was not like a constant job for which a salary was paid; it was a duty dovetailing suddenly upon Poor Law medical officers, a responsible one also, for if they missed a case of small-pox there would be a public outcry. What the Ministry suggested in the case Dr. Bone had mentioned was equal to 2d. per head for the examination, which would make medical practice purely farcical. Anything less than 6d. per head seemed unreasonable.

It was agreed that the matter be left with Dr. Bone (chairman of the Medico-Political Committee), Dr. Hillman (acting-chairman of the Public Health Committee), and Dr. Buchan to confer as to an appropriate scale of payment, and to take such steps as seemed desirable.

#### *By-election of Direct Representatives to General Medical Council.*

Dr. Bone, for the Medico-Political Committee, said that the election of two direct representatives for England and Wales on the General Medical Council would take place shortly to fill vacancies arising from the death of Dr. J. A. Macdonald and the appointment of Sir Robert Bolam to represent the University of Durham on the Council. He moved that the usual procedure in connexion with these elections, as approved by the Annual Representative Meeting in 1915 for a by-election in 1916, be followed.

After some discussion it was agreed to alter somewhat the original procedure. The Divisions would, as usual, be advised by the Medico-Political Committee of the fact of the election, but instead of merely requesting that the matter be taken into consideration by the Divisions they are to be asked to call a meeting of the whole profession in their areas, and to inform the committee by a certain date of the names of any person or persons legally qualified for election whom the meeting might have deemed suitable to be nominated. The rest of the procedure is to follow the usual course, including a special meeting of representatives of Divisions, at the time of the Annual Representative Meeting, to make the final choice.

#### *"Clocking-in" by Medical Officers.*

The Medico-Political Committee had considered a question recently raised in Belfast, where the corporation had adopted automatic time-recording machines, whereby its staff, including medical officers, recorded their time of arrival on duty, and reported that "The committee sees no objection to medical officers being required to record, in common with other

employees of the corporation, their time of arrival on duty on an automatic time recorder, being of opinion that there is no difference in principle between this method and that of signing a book stating the time of attendance."

Dr. Leslie strongly protested against this verdict. The principle of "clocking-in" had hitherto been confined to wage-earners. The hour of arrival and departure might well be left to the honour of a professional man. One medical officer in Belfast had resigned rather than "clock-in." An endorsement by the Council of this practice of "clocking-in" would have far-reaching consequences. He moved:

That the Council objects to medical officers being required to record their time of arrival or departure from duty on a recording machine as is customary among wage-earners, believing as they do that this custom is derogatory.

Sir William Wheeler seconded. The medical officers of the Belfast corporation had, he said, been put in the same position as scavengers. Dr. Buchanan spoke in support of the resolution, but not on any ground of the dignity of the professional man. "Clocking-in" in the case of the wage-earner was for the definite purpose of recording overtime, for which the medical officer did not receive payment. As for dignity, no doubt the street-sweeper had his dignity to maintain just as much as the medical man. Sir Robert Bolam asked whether this was really a matter of serious importance. What real difference was there between a system of this sort, where a man had a key and registered the time he entered the institution, and writing one's name and time of arrival in a book? Dr. Bone said that if the Council felt that "clocking-in" was derogatory it would be necessary to have a full discussion of the circumstances which had arisen in Belfast, where signature in an attendance book had proved unsatisfactory. Dr. Dain said that ever since he was a student the honorary staffs of voluntary hospitals in Birmingham had always "clocked-in."

Appeals were made to the chairman of the Medico-Political Committee to withdraw the paragraph, but he did not see his way to do so. Eventually the motion before the Council being that the report of the Medico-Political Committee (including this paragraph) be approved, Dr. Leslie, instead of his previous resolution, moved as an amendment that the report be approved with the exception of this paragraph, and this was carried.

#### Other Business.

On the question of the Chiropodists (Registration) Bill, which has been introduced into the House of Lords, the Council passed a resolution that it was undesirable that chiropodists should be recognized in a special register, as such register would convey to the public that chiropodists were competent to undertake—to quote from the preamble of the bill—"the diagnosis and treatment of diseases of the feet."

On the motion of Mr. McAdam Eccles the Council agreed to the reprinting for widespread distribution among hospital staffs of the report of the recent Conference on Contributory Schemes, which appeared in the last *Supplement*.

Progress was reported in the preparations for building extensions at Headquarters.

A matter adjourned from the last Council meeting was brought forward again by Dr. Lyndon, chairman of the Central Ethical Committee. This concerned the question of removal from membership of the Association of any medical man whose name had been erased from the Register of a Dominion, Colony, or Dependency. The amended article, as drafted by counsel, was as follows:

9. Membership of the Association may be terminated in any of the following ways—namely:

(c) *Ipso facto* . . . (iii) upon erasure on the ground of professional misconduct from any Medical Register for the time being established for the Irish Free State, or for India or any British Dominion, Colony, or Dependency, or any Province or State forming part thereof respectively, or for any British Protectorate or Mandated Territory.

This was agreed to as a recommendation to the Representative Body.

Dr. Bone, for the International Medical Sea Code Committee, reported that the committee had prepared a simple questionnaire on the signs and symptoms of disease and injuries for the use of master mariners when seeking medical advice by wireless from a surgeon on another ship or on shore. Special thanks were due to Mr. H. S. Sonttar and Dr. H. L. Tidy for the preparation of this questionnaire.

Dr. Bone also reported for the Private Practice Committee,

which had had the advantage of a report by the Medical Secretary on the result of his personal investigations into the health services of certain county, county borough, and other authorities. The report of the committee would be issued to Divisions and Branches probably at the end of 1928 or the beginning of 1929.

Dr. Walker, for the Charities Committee, moved, and it was agreed, that a sum of £332 standing to the credit of the Charities Trust Fund be allocated in certain proportions to the Royal Medical Benevolent Fund, Epsom College, and the Sir Charles Hastings Fund.

The Scottish Committee was authorized to call a conference of representatives of staffs of voluntary hospitals in Scotland to consider hospital policy, and also a conference of secretaries of Branches and Divisions for the more effective organization and stimulation of interest in the work of the Association in Scotland.

Other reports, which dealt only with routine matters and gave rise to no discussion, were submitted by the Journal, Finance, Office, and Organization Committees.

The Council rose at 6.45 p.m.

## Association Notices.

### TABLE OF DATES.

June 30, Sat.	Supplementary Report of Council appears in <i>BRITISH MEDICAL JOURNAL SUPPLEMENT</i> .
July 4, Wed.	Amendments and riders for inclusion in A.R.M. agenda must be received at Head Office by this date.
July 20, Fri.	Annual Representative Meeting, Cardiff, 10 a.m. Nominations for election of 12 members of Council by grouped representatives must be received (at A.R.M., Cardiff) by this date, 2 p.m.
July 21, Sat.	Annual Representative Meeting, Cardiff.
July 23, Mon.	Council, Cardiff.
July 24, Tues.	Annual Representative Meeting, Cardiff. Annual General Meeting, Cardiff, President's Address.
July 25, Wed.	Council, Cardiff. Conference of Honorary Secretaries, Cardiff.
July 26, Thurs.	Meetings of Sections, etc., Cardiff.
July 27, Fri.	Meetings of Sections, etc., Cardiff.

ALFRED COX, Medical Secretary.

### BRANCH AND DIVISION MEETINGS TO BE HELD.

**BIRMINGHAM BRANCH: WEST BROMWICH DIVISION.**—A quarterly meeting of the West Bromwich Division will be held at the Smethwick Committee Rooms, 1, South Road, Smethwick, on Tuesday, June 26th, at 3 p.m., for the consideration of Annual Report of Council and instructions to representative.

**DORSET AND WEST HANTS BRANCH: BOURNEMOUTH DIVISION.**—The annual social meeting of the Bournemouth Division will be held on Saturday, July 14th, when a visit will be paid to the Pitt Rivers Museum, Farnham, Blandford, to be followed by tea at Larra Treo Grounds, Tolland Royal.

**EDINBURGH BRANCH.**—The annual meeting of the Edinburgh Branch will be held at Pathhead Ford on Tuesday, June 26th. Luncheon will be provided in the Hall, Pathhead, at 12.15 for 12.30 p.m. (charge 4s.). Dr. Craig (Pathhead) has obtained the courtesy of the green of the Ford Valley Golf Club for the annual competition (stroke). He has also obtained the courtesy of the Pathhead bowling green. Visits have been arranged for Prestonhall Gardens, Crichton Castle, and Church, and the Voe Nursing Home, the latter by invitation of Professor G. M. Robertson. At 4.30 p.m. Dr. Craig will entertain the party to tea. The business meeting will take place at 5 o'clock. Agenda: Report of Branch, treasurer's business, and annual report; election of officers; presentation of golf competition prizes; report of election of representative to the Central Council; filling of vacancy on the board of the Queen Mary Nursing Home; proceedings of Scottish Committee; Annual Report of Council and Annual Representative Meeting; Power of Branch to appoint additional members to Branch Council under Rule 4 (2) (g).

**LANCASHIRE AND CHESHIRE BRANCH: MID-CHESHIRE DIVISION.**—A meeting of the Mid-Cheshire Division will be held in the board room of the Altrincham General Hospital on Tuesday, June 26th, at 8.30 p.m. Agenda: To instruct representative in the Representative Body. Address by Dr. T. W. H. Garstang entitled "Personal reminiscences of the profession in fifty years, and of the British Medical Association in the last twenty-five years."

**LANCASHIRE AND CHESHIRE BRANCH: ROCHEDALE DIVISION.**—A meeting of the Rochdale Division will be held in the Lyceum (Rochdale Education Committee Offices), Baillie Street, Rochdale, on Wednesday, June 27th, at 8.30 p.m. Business: Annual Report of Council and instructions to representatives.

**METROPOLITAN COUNTIES BRANCH: HENDON DIVISION.**—The next meeting of the Hendon Division will be held at Hendon Cottage Hospital on Friday, June 29th, at 8.30 p.m. Agenda: Clinical meeting, cases and specimens will be shown by Drs. E. B. Morley, J. W. Ensor, R. Hunt Cooke, and Mr. L. G. Phillips. Other members are invited to show cases and specimens at this meeting.

and to notify their intention to the honorary secretary by June 27th.—Consideration of Supplementary Report. Dr. and Mrs. H. R. S. Walford have extended an invitation to members of the Division and their friends to view, from their grounds at Hendon Grove, the Air Pageant on Saturday, June 30th, at 2.30 p.m. Members wishing to attend are requested to notify the honorary secretary as early as is convenient, when personal invitations will be issued.

**METROPOLITAN COUNTIES BRANCH: MARYLEBONE DIVISION.**—A meeting of the Marylebone Division will be held at 11, Chandos Street, Cavendish Square, W.1, on Thursday, June 28th, at 8.15 p.m. Agenda: Annual Report of Council—adjourned discussion; amendments will be proposed by (1) Dr. David Roxburgh, (2) Dr. Graham Little, M.P. Discussion on Lunacy Law Reform, to be opened by Dr. Hawthorne. Instructions to representatives in Representative Body.

**METROPOLITAN COUNTIES BRANCH: NORTH MIDDLESEX DIVISION.**—A meeting of the North Middlesex Division will be held on Thursday, June 28th. This will be a visit to the London factory of Messrs. Oxo, Ltd. Members are asked to meet at 16, Southwark Bridge Road, S.E. (near Southwark Bridge, south side), at 2.30 p.m. The visit will occupy two hours, and afternoon tea will be provided. Arrangements will be made for parking cars. The nearest stations are Mansion House or Cannon Street (5 minutes), Bank or London Bridge (10 minutes).

**METROPOLITAN COUNTIES BRANCH: ST. PANCRAS DIVISION.**—A meeting of the St. Pancras Division will be held at the British Medical Association House, Tavistock Square, W.C.1, on Tuesday, July 10th, at 9 p.m. Dr. W. Camac Wilkinson will read a paper on the home treatment of tuberculosis by the general practitioner.

**METROPOLITAN COUNTIES BRANCH: WANDSWORTH DIVISION.**—Two meetings of the Wandsworth Division will be held in the Town Hall, Wandsworth, to consider the Koch diagnosis and treatment of tuberculosis by means of tuberculin, together with a proposal for a collective investigation into the subject. The first meeting will be held to-day (Friday, June 22nd), at 9 p.m., when Dr. Robert Carswell will read a paper on "History and diagnosis." At the second meeting, on Friday, June 29th, at 9 p.m., Dr. Carswell will read another paper entitled "Treatment, and a proposal for a collective investigation." The meetings will be open to all members of the medical profession.

**NORFOLK BRANCH.**—The annual meeting of the Norfolk Branch will be held at the Town Hall, Aylsham, on Thursday, July 5th, at 3 p.m. Agenda: Report of the Branch Council and annual financial statement; induction of the new president, Dr. B. B. Snppwell, by the retiring president, Sir Hamilton Ballance, K.B.E., C.B.; election of officers; an address by Mr. Vivian Carter, British secretary of Rotary International, on the diagnosis of personality. Tea (to which ladies are invited) at 4.30 p.m., at the Grange, Aylsham, by invitation of Dr. Snppwell and Miss Snppwell.

**NORTHERN COUNTIES OF SCOTLAND BRANCH.**—The annual meeting of the Northern Counties of Scotland Branch will be held at the Station Hotel, Kyle of Lochalsh, on Saturday, June 30th, at 2.5 p.m. Business: Report of election of officers of Branch; report of Branch Council and annual financial statement. Before the meeting members and their guests will lunch together at the hotel at 12.30 p.m. After the meeting there will be an opportunity for those who wish to play golf, and motor boat cruises are also being arranged. For members coming by road who do not wish to take their cars across Dornie Ferry, motor transport will be arranged from there to Kyleakin, leaving the west side of the ferry at 11.45 a.m.

**NORTHERN COUNTIES OF SCOTLAND BRANCH: ISLANDS DIVISION.**—The general meeting of the Islands Division will be held on Saturday, June 30th, in the Station Hotel, Kyle of Lochalsh, at 10.30 a.m., to elect officers and Executive Committee.

**NORTH LANCASHIRE AND SOUTH WESTMORLAND BRANCH.**—The annual meeting of the North Lancashire and South Westmorland Branch will be held on Tuesday, July 3rd, at 3.15 p.m., in the Ethel Hedley Hospital, Calgarth (by kind permission of Dr. Hough and the Governors of the Hospital). Dr. J. Lang Cochrane will deliver his presidential address. Ladies are invited, and a boat on Lake Windermere will be placed at their disposal.

**NORTH WALES BRANCH.**—The annual meeting of the North Wales Branch will be held at the North Wales Sanatorium, Llangwyfan, Denbigh, on Friday, July 6th. The council of the Welsh National Memorial Association and the house committee of the sanatorium will entertain the members to lunch, and a tour of the institution will be made. Agenda and further particulars will be announced later, but members are requested to make a note of the date as a large attendance is hoped for.

**OXFORD AND READING BRANCH.**—The annual meeting of the Oxford and Reading Branch will be held, by kind invitation of the Governors and Medical Superintendent, at Holloway Sanatorium, Virginia Water, on Wednesday, June 27th, at 4.30 p.m. Agenda: Election of officers. A cricket match (St. Thomas's Hospital v. The Sanatorium) will be in progress from 2.30 p.m., and the members may like to have the opportunity of seeing the hospital during the afternoon. Tea 4.45 p.m. In the forenoon the Collier golf cup will be played for at Wentworth. Competitors must play from the competition tees at three-quarters of their lowest handicap. Players are asked to make their own arrangements for partners.

**OXFORD AND READING BRANCH: OXFORD DIVISION.**—The next meeting of the Oxford Division will be held at the Radcliffe Infirmary, Oxford, on Wednesday, June 27th, at 2.30 p.m. Agenda: Correspondence, instructions, clinical cases. Mr. Rose-Innes: Surgery and other pursuits in the islands of Scotland.

**SOUTH WALES AND MONMOUTHSHIRE BRANCH: SOUTH-WEST WALES DIVISION.**—The annual meeting of the South-West Wales Division will be held at the Ivy Bush Hotel, Carmarthen, on Thursday, June 28th, at 3 p.m. Business: Election of officers for the coming year. Agenda for the Annual Representative Meeting and instructions to representative. Nomination from Division of president-elect for South Wales Branch.

**SOUTH-WESTERN BRANCH.**—The eighty-ninth annual meeting of the South-Western Branch will be held on Wednesday, June 27th, at 3.15 p.m., in Bromley's Café, Barnstaple, when Mr. Pickard will resign the chair to Dr. Harper, who will deliver his inaugural address entitled "The influence of William Smellie and William Hunter on obstetric medicine in the eighteenth century." The report of the Branch Council for the year 1927-28, and the financial statement for the year 1927 will be presented to the meeting, and the officers of the Branch for the year 1928-29 will be elected. Luncheon, by invitation of the President-Elect, will be taken at 1 o'clock at Bromley's Café, and after the meeting has concluded tea will be provided. The annual dinner of the Branch, to which medical and non-medical guests and ladies are invited, will be held at 7 o'clock at the café. Tickets, 8s. each (exclusive of wines), may be obtained from Dr. H. C. Jonas, Bouthport Street, Barnstaple. Accommodation for the night could be arranged if notice is given to Dr. H. C. Jonas, Bouthport Street, or Dr. Killard-Leavey, Litchdon House, Barnstaple.

**SURREY BRANCH.**—The annual meeting of the Surrey Branch will be held in the Town Hall, Kingston-on-Thames, on Wednesday, June 27th, at 2.15 p.m. The Kingston-on-Thames Division invites members to lunch at Nuttall's Restaurant at 1 p.m. Colonel C. W. Profeit will address the meeting on the British Empire Cancer Campaign in Surrey, and the president (Dr. H. R. Cran) will deliver his presidential address. After the meeting members will motor to Epsom to visit Epsom College; tea will be taken in Big School. The annual dinner will be held at Reid's Restaurant, Ashley Road, Epsom, at 6.30 for 6.45 p.m. (tickets 7s. 6d., exclusive of wines).

**SUSSEX BRANCH: BRIGHTON DIVISION.**—The next clinical meeting of the Brighton Division will be held at the Royal Sussex County Hospital, Brighton, on Thursday, June 28th, at 3.45 p.m.

**WILTSHIRE BRANCH.**—The annual meeting of the Wiltshire Branch will be held on Wednesday, June 27th, at 3 p.m., at the County Mental Hospital, Devizes, when a British Medical Association Lecture will be given by Mr. W. McAdam Eccles on the treatment of hernia by trusses, illustrated by their actual application.

**WEST SOMERSET BRANCH.**—The annual meeting of the West Somerset Branch will be held at Deller's Café, Taunton, on Saturday, June 23rd, at 12.15 noon. Agenda: Induction of president-elect; annual report; election of officers, Branch Council, and Ethical Committee.

## Meetings of Branches and Divisions.

### METROPOLITAN COUNTIES BRANCH.

The president of the Metropolitan Counties Branch and Mrs. E. B. Turner were "at home" at 21, Westbourne Terrace, W., on June 7th. The guests numbered over 140, and included many members of the Branch, accompanied by their wives, together with Lady Bowly and members of committee of the Royal Medical Benevolent Fund Guild. As Mr. E. B. Turner's term of office as president has now drawn to a close it was pleasant to see so many of his old friends and colleagues, and to observe the esteem and affection in which he is held. The delightful classical singing and pianoforte recitals of Miss Norah Scott Turner and Mr. Greenwood were much appreciated, and a most enjoyable evening was spent.

### METROPOLITAN COUNTIES BRANCH: CAMBERWELL DIVISION.

The annual meeting of the Camberwell Division was held at St. Giles Hospital, 22nd. In the unavoidable absence of the president, the chair was taken by Mr. MASTERMAN.

The annual report was read and approved. The following officers were elected for the ensuing year:

President, Mr. E. W. G. Masterman	R. C.
Harkness, Honorary Secretary, Dr. J.	and
Deputy Representative in Representative	d Dr.
J. H. Clatworthy.	

A delightful address was then given by Mr. JAMES R. OGDEN on the treasures of Tut-ank-Amen's tomb. Several interesting and beautiful slides were shown, including many original photographs taken by the lecturer during his recent visit to Luxor. Dr. BATTEN, proposing the vote of thanks, congratulated Mr. Ogden on giving the most enjoyable address he had ever heard at a Divisional meeting.

### METROPOLITAN COUNTIES BRANCH: CITY DIVISION.

The annual general meeting of the City Division was held at the Metropolitan Hospital on June 5th, when Dr. PHILIP HAMILL was in the chair. Thirty-seven members were present. After the SECRETARY had delivered his report for the past year a very excellent cinematograph entertainment was given by Messrs. Kodak Ltd., including (1) excision of rib for empyema; (2) peristalsis of the different parts of the intestinal canal; (3) trephining as performed by Mr. Souttar; (4) a film demonstrating golf strokes. A hearty vote of thanks was passed to Messrs. Kodak Ltd. and their representatives for the exceedingly interesting show.

A clinical meeting was held at the Metropolitan Hospital on June 8th, when Mr. R. A. RAMSEY showed a most instructive series of cases.

#### METROPOLITAN COUNTIES BRANCH: TOWER HAMLETS DIVISION.

A GENERAL meeting of the Tower Hamlets Division was held on May 29th, at the Limehouse Town Hall, when Dr. E. B. HASTINGS was in the chair.

A letter was read from the secretary of the London Public Medical Service with reference to the suggested fee of 8s. 8d. per head per annum for juvenile Oddfellows, and it was resolved that the Division deprecate this proposal. An invitation from the Wellcome Bureau of Scientific Research for the Division to hold a meeting at the museum was accepted.

It was decided that the question of fees for reports by medical practitioners at the request of coroners should be dealt with by the Metropolitan Branch Council.

The following officers were elected.

*Chairman*, Dr. W. H. F. Oxley. *Vice-Chairman*, Dr. B. Morris. *Honorary Secretary*, Dr. L. Mushin. *Honorary Treasurer*, Dr. M. L. Barrett. *Representative in Representative Body*, Dr. W. H. F. Oxley. *Deputy Representative in Representative Body*, Dr. M. L. Barrett.

On the motion of Dr. MORRIS a vote of thanks was accorded with acclamation to Dr. Hastings for his work in the past as chairman. In reply Dr. HASTINGS said he hoped to maintain his association with the Division.

#### PERTH BRANCH.

At a meeting of the Perth Branch, presided over by Dr. MENZIES, the Report of Council was considered. Paragraph 104, which recommended 8s. 8d. for attendance on juveniles, was not approved, as it was felt that future private negotiations with the Government would be hindered if the profession accepted less than the yearly panel fee. Objection was also taken to the paragraph relating to paying centres for infant hygiene. With reference to assistant medical officers to mental hospitals, the opinion was expressed that the diploma in psychological medicine should be under the control of the General Medical Council, and also that a man who had previously been a house-physician was preferable, as regards salary, to a man holding the diploma.

Dr. Haig (Crieff) was appointed representative in the Representative Body, and Dr. Low deputy representative.

#### STAFFORDSHIRE BRANCH.

A MEETING of the Staffordshire Branch was held on May 17th at the Victoria Hotel, Wolverhampton, when Dr. J. A. M. CLARK, chairman of the Branch, was in the chair, and there were twenty members present. Mr. S. W. MASLEN JONES read a paper on uterine infection, dealing particularly with the treatment of acute puerperal infection of the uterus by means of glycerin. He laid stress on the importance of the details of the technique of introducing the glycerin into the uterus, particularly with regard to (1) the adoption of the lithotomy position, and (2) the avoidance of volsellum forceps for manoeuvring the cervix into position, which is done by manipulation. The advantages of this method of treatment were then dealt with, and finally its use in chronic infections of the uterus. The paper was followed by a brisk discussion. Dr. S. C. DYKE showed a series of pathological specimens, including a kidney with a tuberculous lesion which had healed naturally, an enormous hydatid cyst of the ovary which had caused obstruction in labour, and a carotid tumour. Mr. W. F. CROSBY also showed two pathological specimens, a large vesical calculus which had caused no bladder symptoms, and a collection of long thin gall-stones removed from a gall-bladder which had been drained some years before the present operation.

#### SURREY BRANCH: GUILDFORD DIVISION.

The annual meeting of the Guildford Division was held at the Royal Surrey County Hospital on June 7th, when Mr. H. B. BUTTER was in the chair. Dr. W. F. Fleming was elected chairman and Dr. J. McGlashan vice-chairman for the ensuing year, and Mr. Bluett was desired by the meeting to continue as honorary secretary.

Dr. Charles C. Scott was nominated as president-elect of the Surrey Branch, subject to his consenting to serve, and Dr. Conor H. Donaldson was elected an associate member of the Division.

The annual report of the Executive Committee was adopted. A discussion took place on the contributory scheme which is being instituted in West Surrey by the newly formed Hospital League. The honorary secretary was nominated as a representative on the committee, and instructed to report the progress of the scheme, and especially to emphasize that recognition should be made of the services of the medical staffs of the hospitals included.

The Annual Report of Council was considered and the representative instructed.

It was reported that Dr. H. P. Gabb, who was the winner of the Treasurer's Golf Cup competition on May 23rd, is eligible to play in the final at Cardiff.

#### YORKSHIRE BRANCH: HARROGATE DIVISION.

On June 13th the CHAIRMAN and Mrs. MORRIS were at home to members of the Division at the Harlow Manor Hydro. Some sixty members and their wives were present at tea, which was held in the ballroom. Afterwards the company took full advantage of the facilities afforded them in the grounds for playing tennis, croquet, bowls, and putting golf.

## NOTICES OF MOTION BY DIVISIONS FOR THE ANNUAL REPRESENTATIVE MEETING, CARDIFF, 1928.

### *Appreciation of Deceased Members.*

By BRIGHTON: That it be referred to the Council to consider and report whether, and if so in what manner, it would be possible for the Association to place on permanent record from time to time its indebtedness and appreciation of deceased members—who by their outstanding contributions of voluntary medico-political and medico-sociological services for the maintenance of the honour and interests of the medical profession merit such record—in such a manner as at the same time to encourage others of its members to like services.

### *Payment of Expenses of Group Representatives.*

By BRIGHTON: That (with reference to the recommendation contained in para. 61 of the Annual Report of Council) in order to allow of expenses of Group Representatives attending Representative Body being paid as contemplated under new By-law 32A (3), there be added after the words "meetings of Council" in new Article 42 (2) the words "or of the Representative Body."

By BRIGHTON: That (with reference to the recommendation contained in para. 61 of the Annual Report of Council) in order to allow the expenses of Group Representatives attending Committees being paid as contemplated by new Article 42 (2) the words "or of Committees" be added after the words "of the Council" in new By-law 32A (3).

### *Paying Centres for Infant Hygiene.*

By BRIGHTON: That the Representative Body disagrees with the conclusions and recommendations contained in paragraph 95 of the Annual Report of Council, and adopts the following resolution, which was the view of the Council in 1917—namely:

That while it fully appreciates the value of any educational work proposed to be undertaken at paying centres for middle-class mothers in the way of giving lectures on infant management, it does not approve of these centres providing consultations and advice in respect of mothers and young children belonging to classes of the community who are quite able to consult their own family doctor.

By HAMPSTEAD: That (with reference to Recommendation A contained in paragraph 95 of the Annual Report of Council) the Representative Body regards the subject of infant hygiene as an essential part of general medicine; that it urges general practitioners to be prepared to advise their patients upon it when consulted, and is opposed to the setting up of the proposed "paying centres" as being subversive to the principles of family practice.

By HAMPSTEAD: That (with reference to paragraph 95 of the Annual Report of Council) in the opinion of the Representative Body practical instruction in the subject of infant hygiene should form part of the clinical education of all medical students.

### *Lunacy and Mental Disorder.*

By BRIGHTON: That generally throughout the Memorandum on the Report of the Royal Commission on Lunacy and Mental Disorder as regards England and Wales (see Appendix V to Annual Report of Council), where reference is made to institutional treatment words be added which will indicate that the various places mentioned at commencement of paragraph 6 of that Memorandum are referred to.

By BRIGHTON: (i) That it be made clear in paragraph 4 of the Memorandum on the Report of the Royal Commission on Lunacy and Mental Disorder as regards England and Wales (see Appendix V to Annual Report of Council) that the out-patient departments suggested are not the ordinary ones at present at voluntary hospitals; and (ii) that the word "special" be inserted before the words "out-patient department."

By BRIGHTON: That it is not desirable, as contemplated in paragraph 17 of the Memorandum on the Report of the Royal Commission on Lunacy and Mental Disorder as regards England and Wales (see Appendix V to Annual Report of Council), to do away with the intervention of a magistrate or some public official where the patient is not capable of volition.

### *Scheme for Co-ordination of Hospital Provision.*

By BRIGHTON: That the Representative Body go into Committee to consider the scheme for co-ordination of hospital provision (see Appendix VII to Annual Report of Council) and subsequently consult the Infirmary Medical Superintendents Society before finally adopting the Report.

## Correspondence.

*Association Professionnelle Internationale des Médecins.*  
(A.P.I.M.)

SIR,—An appeal has been made to the British Medical Association by this young, but active, association, which, if we remember the early struggles of our own body, might have fallen upon more sympathetic ears. The Association Professionnelle Internationale des Médecins (A.P.I.M. for short) is a society which aims at being in medical politics for Europe what we are for the Empire—the body which can speak for the united profession. It is a great idea, and we may be proud of the fact that its inception was the thought of an ordinary country doctor outside Paris. That it is meeting a demand seems clear from the fact that, though it has only existed for eighteen months, twenty-four countries have joined it, while other nine are in correspondence with it. Finland and Russia alone have definitely refused, the former through having no official body through which to deal; so if we stay out we shall be in good company. Not only does the majority of the profession in Europe see the possibilities; these are recognized by others as well. The League of Nations is accepting it; its International Labour Office, through M. Maurette, the director, has said that the formation of a body like the A.P.I.M. was desirable in order that it might be consulted on “fundamental medical questions.” The International Association of Benefit Societies is also watching it, and our “opposite number” in Britain, the Association of Benefit Societies, is represented by Messrs. Canter and Rockliff, names not unfamiliar to us. With these facts before us it is quite clear that the A.P.I.M. may prove to be a necessity for the welfare of the profession; it will certainly fulfil a useful function in connexion with the League, and incidentally will have up against it the full power of the Association of Benefit Societies.

Now such an organization deserves all the help that it can get, and no one is more able to help it than we of the British Medical Association. Our Association is in a very splendid position. Recognized within the Empire as the mouthpiece of the profession, regarded with respect not unmixed with envy by the great trade unions, it is the ideal society to which the A.P.I.M. looks, whose experience and prestige it invokes, and whose comradeship it would wish to have.

How has the Council met its overtures? With the caution proper to any breaking of new ground the Council was a little timid as to having any dealings with the infant body; but a more courageous instinct moved it to send over Dr. Cox as an observer to the general meeting last September. He went quite prepared to be critical. He returned with the definite opinion that this is a sound proposition, and said so in the excellent report with which he furnished the Council, a report which, in my opinion, should have been sent down to Divisions before any decision was come to. He, at any rate, has no doubts.

“I am of opinion that our Association ought to belong to the A.P.I.M. . . . I felt that there was a good deal to be said for the view (which I put forward as plainly as I could at the Congress) that it was doubtful whether the new body could really do anything which could not be done by the usual collaboration between friendly bodies and officials. . . . But having been at the Congress, and having heard what the other representatives had to say, and particularly having in view the recognition which is going to be given to the body by the International Labour Office, and the necessity of having something to act as ‘opposite number’ to the new international ‘approved society’ organization, I hardly see how we can afford to remain outside.”

Such was the considered opinion of our Medical Secretary: but the Council put it aside. The new body was too young. Foreigners had a different standpoint from ours. And it was to cost £125 per annum more. For these reasons, following an adverse opinion of the Finance Committee, they turned it down. That is their definite opinion, and I think they are wrong.

For one thing, I do not think that so important a departure should be settled *in camera*, so to speak, by the Council. Clearly, in my submission, the sanction of the Representative Body should have been sought. But apart from that, on the merits of the case, my contention is

that this is not a financial matter. It is a matter of the honour and prestige of the Association, and, through it, of the nation. There stands an appeal to us to help our less fortunate brethren with our greater experience and skill in the management of medical affairs. It is an opportunity we have never had before, and may never have again. Last September Dr. Cox was appealed to by the entire Congress, especially by Germany, whose representative, if we do not go in, will be the dominant power; it was a fine gesture on his part. The Americans, true to their policy of isolation, are not in yet, but are to be guided by Britain. At that moment, in my view, the British Medical Association stood at a higher point than it has ever reached in its history, with the entire profession of Europe turning to it for help and for guidance. Dr. Cox came home convinced. He drew up the report, which left no doubt as to his views.

The Council quite properly considered the financial aspect, and—unfortunately, as I think—gave too much credence to the tale of expense. What, to us, is £125 per annum? Less than 1d. a head; possibly it might run to 1d. if the thing expands. But this is not a question we should decide on the money aspect. We exist for the welfare of the profession, not in the narrow, but in the broadest, sense. But even from the money point of view it might not be all loss. There are in Europe about 250 men on the *British Medical Register*. Practically none of these are our members. If we take a hand in the A.P.I.M. we might pick up many of these, and get some to act for us. That might be considered.

But history will have to repeat itself one way or the other. There are two trends. The one is that of Bright and Cobden, the strictly insular position that avoids “entangling alliances,” the one that has already brought on us the scorn of Napoleon as “a nation of shopkeepers” and the epithet of “perfidious Albion,” a school of thought that one had hoped was dead. There is the other which, looking beyond these shores and above material interests, which helped everywhere the fight for freedom, destroyed the slave trade, took its part in the liberation of Greece and of Italy. Which of these lines shall we follow, for follow one we must? I appeal once again to the Council and to the Association to adopt a policy which shall be in accord with the great traditions of British statesmanship—the succour of the weak wherever they may be. And anyone who reads the report will agree that, in comparison with ourselves, the medical men abroad are woefully bound down, and that our help would be of great advantage to them. The Brighton Division asked for and received a copy of the report, and I believe that any other Division may have one on application. I hope that in some way we may be able to ventilate this most important subject at the Annual Representative Meeting.—I am, etc.,

St. Andrews, June 17th.

C. E. DOUGLAS.

*Infectious Diseases and State Insurance.*

SIR,—It may be of interest to members of our profession to know that State-insured persons are not secured against infectious diseases. By this I mean that local authorities throughout the country have the right to determine what should, or should not be, notifiable. An example of this is to hand.

A few days ago two sisters contracted measles. On the fourth day one developed complications of such a nature that immediate removal to a fever hospital was absolutely necessary as well as imperative. On telephoning the “authority,” I was informed that measles was not on the notifiable list, but that the patient could be admitted at a charge of £3 3s. a week. This the patient could not afford to pay, and as a trained nurse was also out of the question the sequel was obvious. One could not see a patient die without a struggle, so it ended in the fees being guaranteed for a fortnight. On the strength of this the patient was admitted. Unfortunately the time expires on June 22nd, and, although at the hour of writing, the case has taken a favourable turn, I cannot imagine the patient being discharged on that date as convalescent. Who, then, is to be responsible for future charges?

It is nothing less than a grave scandal that such a state of things should exist. When we consider, too, the fact that measles has become a serious complaint, affecting adults as well as children, and when we consider the various complications that may arise, it is obvious that it should be notifiable

throughout the country. We know that the finances of hospitals have suffered grievously through the Insurance Act, and that contributions from insured patients are necessarily imperative, but that this should happen is beyond both reason and logic.—I am, etc.,

Canford Cliffs, June 12th.

FRANCIS G. BENNETT.

#### Examination of Vagrants for Small-pox.

SIR,—Dr. J. S. Clarke's letter in the *Supplement* of June 9th (p. 247) is very much to the point. Here, too, one quarter was paid for in April. I arranged with the board of guardians in February to do the inspections for 7s. 6d. per day. This was sanctioned by the Ministry of Health.

The daily number of vagrants here is anything from 6 to 30, average, say, 20. The men are stripped and lined up in readiness, and the inspection seldom takes as much as five minutes. The casual ward is just under half a mile from my house. On foot I take twenty minutes to get there and back and do the inspection, fifteen minutes on a bicycle, or ten minutes by car. I do the inspection at 7.45 a.m. In the winter it makes a welcome object for a short walk before breakfast. At this time of the year I do it on my way back from my morning swim, and get up perhaps a quarter of an hour earlier in order to fit it in.

I consider 7s. 6d. a sufficient fee. The remuneration suggested by the Public Health Committee would work out at about 20s. a day here. Anxious though I am to support the British Medical Association, I have not the courage to apply for this.—I am, etc.,

Blandford, Dorset, June 12th.

L. BODLEY SCOTT.

### National Insurance.

#### LOCAL MEDICAL AND PANEL COMMITTEES.

##### COUNTY OF SURREY.

At the meeting of the County of Surrey Panel Committee on March 16th, under the chairmanship of Dr. ARNOLD LYNDON, an interesting point arose with regard to a Surrey insurance practitioner who had received a request from the Insurance Committee that he should refund money which had been overpaid him, owing to a clerical error in the office of the committee, since the end of 1921. The practitioner had been paid on 200 more names than were on his list. It appeared that no scrutiny of the register had been made since 1921 until recently, when it was discovered that five other practitioners had been paid on wrong data, three of whom had been overpaid and two underpaid. Dr. ANDERSON, the secretary of the Insurance Acts Committee of the British Medical Association, was of opinion that under the distribution scheme, which formed part of the practitioners' agreement with the Insurance Committee, the case for refunding was clear, but he considered that the Insurance Committee had been very negligent in not having had the register examined more frequently, and advised that the representatives of the Panel Committee should raise the matter at the next meeting. The practitioner who had been overpaid explained that he had always accepted the Insurance Committee's figures as correct. The error occurred at the very end of 1921, when the capitation fee was 11s., but in that first quarter the increase received was only £7 above what he had been receiving previously, and he had not noticed that it was higher. Subsequent payments were made at the lower capitation fee of 9s. 6d., so that the chance of detecting the error diminished. The Panel Committee agreed, on the motion of Dr. DANIEL, seconded by Dr. MORRIS MACKENZIE, to ask its executive to frame a protest to be sent to the Surrey Insurance Committee at its next meeting, to make an earlier scrutiny of the register, and to request the Ministry of Health to receive a deputation from the Panel Committee for the purpose of discussing the question.

##### COUNTY OF NORFOLK.

At a recent meeting of the Norfolk Local Medical and Panel Committees, under the chairmanship of Dr. B. D. Z. WRIGHT, it was reported that under the mileage scheme for 1927 the amount allocated was, for general mileage, £9,430, and for special mileage, £935. The scheme was approved. The question was raised as to the scaling down of the mileage, and the secretary was instructed to ask the clerk of the Norfolk Insurance Committee on what principle the mileage was estimated.

##### COVENTRY.

At its meeting on June 5th, with Dr. ARTHUR HAWLEY in the chair, the Coventry Panel Committee adopted a vote of sympathy and condolence with the relatives of Dr. Arthur Reginald Pittard, who died recently after a short illness. Dr. Pittard was a leading insurance practitioner in the city, and had been a member of the Panel Committee for over eight years. It was reported that consequent upon the extension of the city boundary the preparation of a scheme for paying mileage had become necessary, the enlarged area of the county borough of Coventry being some three times the size of the old city, and a scheme was accordingly considered and approved. Claims for special competence which were allowed included the service of enucleation of tonsils and the injection of varicose veins for varicose eczema.

### Naval and Military Appointments.

#### ROYAL NAVAL MEDICAL SERVICE.

Surgeon Commanders G. D. Walsh to the *President* for Medical Department, temporary; G. H. Innes to the *Barham* on commissioning; G. Carlisle to the *Victory* for R.N. Hospital, Haslar; H. F. Briggs to the *Kent* on commissioning; D. H. C. Given to the *Tamar* for Singapore Naval Base, as Medical Officer in Charge of Medical Organization and as Naval Health Officer.

Surgeon Lieutenant Commanders J. W. Tighe to the *Fisgard*, temporary; W. E. Heath to the *Colombo*; A. E. Phillips to the *Titanic* on relief.

Surgeon Lieutenants C. H. Egan to the *Barham*; J. Hamilton to the *Victory*; E. T. S. Rudd to the *Victory* for R.N. Barracks, Plymouth; W. P. L. McIntyre to the *Field* for Plymouth.

Surgeon Lieutenants (short service) R. C. May, M.C., has transferred to the permanent list.

Surgeon Lieutenants (short service) and appointed to the *Victory* for R.N. Hospital, Haslar, for course of instruction.

#### ROYAL NAVY VOLUNTEER RESERVE.

Surgeon Lieutenant W. Cathiness to be Surgeon Lieutenant Commander, Surgeon Lieutenant W. F. Lascelles to the *Victory* for R.N. Hospital, Haslar, additional, for training.

Probationary Surgeon Sub-Lieutenant A. Elliott to the *Champion* for training.

#### ROYAL ARMY MEDICAL CORPS.

Lieut.-Colonel R. V. Cowey, D.S.O., having attained the age limit for compulsory retirement, retires on retired pay.

Major L. V. Thurston, D.S.O., to be Lieut.-Colonel vice Lieut.-Colonel R. V. Cowey, D.S.O., to retired pay.

#### SUPPLEMENTARY RESERVE OF OFFICERS.

##### ROYAL ARMY MEDICAL CORPS.

Lieutenant F. W. Oldershaw to be Captain.

#### ROYAL AIR FORCE MEDICAL SERVICE.

Flight Lieutenant J. A. Perdan relinquishes his temporary commission on completion of service and is permitted to retain his rank.

Flying Officers J. H. Cullinan to the Aeroplane and Armament Experimental Establishment, Martlesham Heath; T. A. Edwards to No. 3 Flying Training School, Grantham; A. R. French to R.A.F. Base, Gosport; P. J. Nahan to No. 2 Flying Training School, Digby; B. A. Porritt to No. 5 Flying Training School, Sealand.

#### INDIAN MEDICAL SERVICE.

Major R. L. Vance is appointed to officiate as an Agency Surgeon and is posted as Chief Medical Officer, Western India States Agency and Residency Surgeon, Rajkot.

#### TERRITORIAL ARMY.

##### ROYAL ARMY MEDICAL CORPS.

Captain J. D. M. Cardell resigns his commission.

Lieutenant D. T. McDonald (late Northumberland Fusiliers) to be Lieutenant.

General Hospitals.—Lieutenant H. Miller to be Captain, with precedence as from June 15th, 1927.

#### TERRITORIAL ARMY RESERVE OF OFFICERS.

##### ROYAL ARMY MEDICAL CORPS.

Captain A. F. G. Guinness from Active List to be Captain.

Lieutenant J. W. Mirdoch from Active List to be Lieutenant.

General Hospitals.—Major T. H. W. Alexander, having attained the age limit, relinquishes his commission and retains his rank.

### VACANCIES.

ABERDEEN ROYAL INFIRMARY.—Junior Assistant Ophthalmic Surgeon.

BIRMINGHAM UNIVERSITY.—(1) Assistant Lecturer in Physiology. (2) Assistant Lecturer in Biochemistry in the Physiology Department. Stipend £300 per annum each.

BOMBAY: CHINA AND ALLESTON HOSPITAL FOR WOMEN AND CHILDREN.—Medical Officer in Charge (ad-mensum for officer of Asiatic per mensem as overseas pay) £20

BOURNEMOUTH: ROYAL VICTORIA AND WEST HANTS HOSPITAL.—Third House-Surgeon and Casualty Officer (male). Salary at the rate of £120 per annum.

BRADFORD CITY: Assistant School Medical Officer (male). Salary £600 per annum.

BRIGHTON: SUSSEX THROAT AND EAR HOSPITAL.—Honorary Surgeon.

CHICHESTER: ROYAL WEST SUSSEX HOSPITAL.—Honorary Assistant Surgeon to the Throat, Nose, and Ear Department.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.L.—Surgeon to the Ear, Nose, and Throat Department.

EDINBURGH: ROYAL EDINBURGH HOSPITAL FOR SICK CHILDREN.—Five Honorary Resident Medical Officers.

GLOUCESTERSHIRE ROYAL INFIRMARY AND EYE INSTITUTION.—Resident Surgical Officer (male). Salary £175 per annum.

HULL ROYAL INFIRMARY.—(1) Assistant House-Surgeon (male). (2) Casualty House-Surgeon. Salary £150 and £130 per annum respectively.

KENSINGTON BOARD OF GUARDIANS.—Assistant Medical Officer (male) at St. Mary Abbott's Hospital. Salary £250 per annum.

KENSINGTON, FULHAM, AND CHELSEA GENERAL HOSPITAL.—Junior Resident Medical Officer. Salary at the rate of £100 per annum.

KIDDERMINSTER AND DISTRICT GENERAL HOSPITAL.—House-Surgeon (male). Salary £150 per annum.

KIRKBY: BALFOUR HOSPITAL.—Surgeon and Consultant for the County of Orkney and Superintendent of the Balfour Hospital. Salary £600 per annum.

**LANCASHIRE COUNTY COUNCIL.**—Junior House-Surgeon (woman) at the Biddulph Grange Orthopaedic Hospital. Salary £150 per annum.

**MANCHESTER UNION.**—Junior Resident Assistant Medical Officers at (1) The Withington Hospitals and Institution; (2) Crumpsall Infirmary and Institution; (3) Booth Hall Infirmary for Children. Salary at the rate of £275 per annum each.

**MANCHESTER UNIVERSITY.**—Reader in Materia Medica and Therapeutics. Stipend £800 per annum.

**NEWARK HOSPITAL AND DISPENSARY.**—Resident House-Surgeon (male). Salary at the rate of £150 per annum.

**NORFOLK AND NORWICH HOSPITAL.**—Honorary Physician.

**OPPORT: BRITISH HOSPITAL.**—Medical Officer. Salary £150 per annum.

**PRESTON AND COUNTY OF LANCASTER ROYAL INFIRMARY.**—(1) House-Physician. (2) House-Surgeon. Salary £190 and £150 per annum respectively.

**PRINCESS LOUISE KENSINGTON HOSPITAL FOR CHILDREN, W.10.**—Honorary Anaesthetist.

**ROYAL FREE HOSPITAL, Gray's Inn Road, W.C.1.**—Junior Clinical Assistants.

**ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad Street, W.C.2.**—Refraction Assistant. Salary at the rate of £100 per annum.

**SHEFFIELD UNION HOSPITAL.**—Resident Assistant Medical Officer. Salary £250 for first year, rising to £300 for second year.

**SHETLAND: PARISH COUNCIL OF TINGWALL, WHITENESS, AND WEISDALE.**—Parish Medical Officer and Parochial Vaccinator. Salary from Parish Council £56 per annum.

**STOCKPORT INFIRMARY.**—House-Surgeon. Salary £175 per annum.

**SURREY COUNTY COUNCIL.**—(1) Deputy County Medical Officer of Health. (2) Assistant Medical Officer. Salary for (1) £1,000 per annum; and for (2) £900 rising to £700.

**SWANSEA COUNTY BOROUGH.**—Assistant Dental Surgeons. Salary £450 per annum, rising to £550.

**URRAY PARISH COUNCIL.**—Medical Officer and Parochial Vaccinator. Salary £50 per annum and vaccination fees.

**WILLENDEEN GENERAL HOSPITAL, Harlesden Road, N.10.**—Resident House-Surgeon (male, unmarried). Salary at the rate of £100 per annum.

**WOOLWICH UNION.**—Second Assistant Medical Officer at the Plumstead and District Hospital (male, unmarried). Salary £350, rising to £400.

**CERTIFYING FACTORY SURGEONS.**—The following vacant appointments are announced. Banchory Tarn (Lancashire), Salford (Lancashire), Ilkington (Lancashire), applications to the Chief Inspector of Factories, S.W.1.

*This list of vacancies is compiled from our advertisement columns, where full particulars will be found. To ensure notice in this column advertisements must be received not later than the first post on Tuesday morning.*

### APPOINTMENTS.

**KELLET, Frank, M.A., M.B., B.Ch.Cantab., M.R.C.S., L.R.C.P.,** Assistant Pathologist to the Laboratories of Pathology and Public Health, Harley Street, W.1.

**PETERLIN, F. G. T., M.B., Ch.B.Aberd.,** Certifying Factory Surgeon for the Kirkwall District, Orkney.

**SINCLAIR, W. A., M.B., Ch.B.,** Medical Referee under the Workmen's Compensation Act, 1925, for the Orkney District.

### DIARY OF SOCIETIES AND LECTURES.

**ROYAL SOCIETY OF MEDICINE.**  
*Section of Urology.*—Special Meeting, Thurs., 2 p.m., Operations at St. Peter's Hospital, 8.30 p.m. (at 1, Wimpole Street) paper by Professor Jurasz (Poznan) Movable Kidney, to be followed by a discussion, Fri., 11 to 12 a.m., Demonstration of Special Instruments at 1, Wimpole Street, 2 p.m., Operations at St. Thomas's Hospital, 8.30 p.m., President's Dinner at Verrey's Restaurant.

*Section of Disease in Children.*—Provincial Meeting, at the Royal Infirmary, Leicester, Sat., 2 p.m., Dr. H. Stanley Banks: Treatment of Toxic Diphtheria by Large Intravenous Doses of Antitoxin, 2.30 p.m., Mr. C. H. Bond: Effect of Certain Radiated Sterols on the Cellular Constituents of the Blood, 3.15 p.m., Dr. G. Brittain Gill: On Calcium Deficiency and its Treatment, 3.30 p.m., Cases, 4.30 p.m., Tea in the Honorary Staff Room, 5 p.m., Discussion.

### POST-GRADUATE COURSES AND LECTURES.

**FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.**—Royal National Orthopaedic Hospital, Great Portland Street, W.—Special Clinical Demonstration in Surgery in Out-patient Department, Tues., 2.30 p.m. No fee. *Royal Eye Hospital*, St. George's Circus, S.E.1.—Special Clinical Demonstration in Ophthalmology, Wed., 3 p.m. No fee. *West-End Hospital for Nervous Diseases*, Welbeck Street, W.1.—Special Course of Lectures and Clinical Demonstrations upon Selected Cases for four weeks, 5 p.m. daily, Fee, £2 2s. *London Temperance Hospital*, Hampstead Road, N.W.1.—Practitioner's Course in Medicine, Surgery, and the Special Departments, 4.30 to 5 p.m. daily. Second week. Copies of all syllabuses sent on application, also details of general course of instruction, and specimen copies of the *Post-Graduate Medical Journal*. Apply Secretary, Fellowship of Medicine, 1, Wimpole Street, W.1. Mayfair 2256.

**JOINT TUBERCULOSIS COUNCIL.**—Special Course at Lord Mayor Treloar Cripple's Hospital and College, Alton. Monday to Saturday.

**NORTH-EAST LONDON POST-GRADUATE COLLEGE**, Prince of Wales's General Hospital, Tottenham, N.15.—Mon., 2.30 to 5 p.m., Medical, Surgical, and Gynaecological Clinics; Operations, Tues., 2.15 p.m., Demonstration of Medical Cases; 2.30 to 5 p.m., Medical, Surgical, Throat, Nose, and Ear Clinics; Operations, Wed., 2.30 to 5 p.m., Medical, Skin, and Eye Clinics; Operations, Thurs., 11.30 a.m., Dental Clinics; 2.30 to 5 p.m., Medical, Surgical, and Ear, Nose, and Throat Clinics; Operations, Fri., 10.30 a.m., Throat, Nose, and Ear Clinics; 2.30 to 5 p.m., Surgical, Medical, and Children's Diseases Clinics; Operations.

**ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.**—St. John's Hospital, Leicester Square, W.C.2, Wed., 4.15 p.m., Annual General Meeting (tea at 4 p.m.). Agenda: To receive Reports of Honorary Treasurer, Honorary Secretary, and Elect Officers and Council. To be followed by Ordinary Meeting, Admission of Fellows, Clinical Cases.

**ST. PAUL'S HOSPITAL**, Endell Street, W.C.2.—Thurs., 4.30 p.m., Diagnosis and Treatment of Renal and Ureteric Calculi.

**LIVERPOOL UNIVERSITY CLINICAL SCHOOL ANTE-NATAL CLINICS.**—Royal Infirmary: Mon. and Thurs., 10.30 a.m. Maternity Hospital: Mon., Tues., Wed., Thurs., and Fri., 11.30 a.m.

**SHEFFIELD UNIVERSITY POST-GRADUATE CLINICS.**—At Jessop Hospital, Tues., 3.30 p.m., Gynaecological Cases. At Royal Hospital, Fri., 3.30 p.m., Surgical Cases.

Norfolk Branch: Annual Meeting, Town Hall, Aylsham, 3 p.m.

### BIRTHS, MARRIAGES, AND DEATHS.

*The charge for inserting an announcement of Births, Marriages, and Deaths is 2s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.*

#### BIRTHS.

**BRITAIN.**—On June 14th, at The Elms, Sutton Road, Walsall, to Jenny Simpson, M.B., Ch.B., wife of Bert Britain, a daughter.

**GILL.**—On June 9th, at the Mission Station, Cona Bay, Papua, Iona (née Campbell), the wife of Cecil E. C. Gill, M.B., Ch.B.Ed., of a son (David Ian).

**WESTON.**—At 50, Westgate, Gnisborough, Yorks, on June 6th, to Dr. and Mrs. Cuy Weston, a daughter.

#### MARRIAGES.

**HOBBS—SCRIVEN.**—On June 12th, 1928, at St. Mary's Church, Frensham, Surrey, by the Rev. Rowland Scriven, M.A., uncle of the bride, assisted by the Rev. M. C. H. Collet, M.A., Vicar of Frensham, Frank Bedo Hobbs, M.D., M.R.C.P., of Downing Street, Farnham, Surrey, to Elsie Fetherstonhaugh, only daughter of G. Scriven, M.D., B.Ch., and Mrs. Scriven of Brown Cables, Lower Bourne, Surrey.

**TAYLOR.**—On June 14th, by licence, Arthur Walford Taylor, of Trinity Street, Norwich, elder son of Dr. The Close, Norwich, to Iris Desirée, late Alfred Haldinsein, J.P., and Mrs. Norwich.

#### DEATHS.

**GILLIES.**—At 14, Adross Street, Inverness, on June 13th, 1928, Kenneth Gillies, M.A., M.B., C.M.

**MACDOUGALL.**—On June 12th, after an operation, John Aymers MacDougall, M.D. F.R.C.S.E., of The Hill, Balerno (formerly of Letterewe-Cannes),

# SUPPLEMENT TO THE BRITISH MEDICAL JOURNAL.

Every Member is requested to preserve this "Supplement," which contains matters specially referred to Divisions, until the subjects have been discussed by the Division to which he or she belongs.

### MATTERS REFERRED TO DIVISIONS.

## British Medical Association.

### SUPPLEMENTARY ANNUAL REPORT OF COUNCIL, 1927-28.

	PAGE		PAGE
Preliminary ...	277	Dr. Wm. Robert Yeates	A Vice-President of the Southern Branch and a Chairman of the Southampton Division.
Building ...	278	Ives	A Representative and Assistant Secretary of the Cardiff Division. A Vice-President of the Section of Laryngology and Otology at the forthcoming Annual Meeting at Cardiff.
Organization ...	279	Mr. Archibald Mason Jones	Member of Council, Chairman 1913 to 1920. Chairman of Representative Body, 1907 to 1909. Chairman of Journal Committee. President of Section of Medical Sociology, 1910.
Medico-Political ...	280		
Public Health and Poor Law ...	281	Dr. James Alexander	A President of the Northern Counties of Scotland Branch.
National Health Insurance ...	282	Macdonald	A President of the Aberdeen Branch.
Hospitals ...	283		
Naval and Military ...	284	Dr. John Wm. Mackenzie	A Secretary of the Inverness Division. A Vice-President of the Northern Counties of Scotland Branch.
Medical Benevolence ...	284	O.B.E.	A Member of Council. A Member of the Public Health, Medico-Political and Parliamentary, and Arrangements Committees. A Chairman and Representative of the Bradford Division. President of Section of Medical Sociology, 1924.
Oversea Branches ...	284	Dr. Arthur Manknell	A Chairman of the Northamptonshire Division.
<b>APPENDIX.—National Insurance Defence Trust Balance Sheet and Income and Expenditure Account, 1927 ...</b>	<b>286</b>	Dr. John More	A Member of the Border Counties Branch Council.
		Dr. Tom Dryden Nicholson	A Chairman of the North Lincolnshire Division.
		Dr. Arthur Alfred Pratt	A Chairman of the North Lincolnshire Division.

### Preliminary.

#### OBITUARY.

157. The following is a supplementary list of Members whose deaths the Association deplores:—

Name.	Offices held in the Association.
Dr. Ardeshir Koyaji	Member of Bombay Branch Council.
Dr. James Will Cook	A Chairman of the Bury Division.
Dr. Timothy Corkery	A Member of the Executive Committee of the Chesterfield Division.
Dr. Thomas Augustus Davidson	A Member of the Ulster Branch Council.
Mr. Wm. James Foster	A President of the Oxford and Reading Branch.
Dr. Alfred Charles Edward Harris	A President of the Lancashire and Cheshire Branch and a Chairman and Representative of the Birkenhead Division.
Dr. Wm. James Howarth, C.B.E.	A Member of the Public Health, and Insurance Acts Committee.

Name.	Offices held in the Association.
Dr. George Edward Shuttleworth	Member of Council, 1899-1903. Member of Parliamentary Bills Committee, a President of the Lancashire and Cheshire Branch, a Vice-Chairman of the Hampstead Division and a Member of the Metropolitan Counties Branch Council. Secretary, 1883, and Vice-President, 1885 and 1906, of Section of Psychology.
Mr. Thomas Waddelow Smith	Secretary of Section of Neurology and Psychology, 1926.
Dr. William Snodgrass	Member of Council 1919-22. A Chairman of the Glasgow North-Western Division, a Chairman of Scottish and a Member of Arrangements Committees.
Dr. John Barclay Stewart	A Chairman of the Bury Division.
Dr. David Lewis Williams	A Chairman of the South West Wales Division.
Dr. Allan Huston Adams, Dr. Albert James Beesley, Dr. John Mcara Burke, Dr. Oliver Carlyle, Dr. John Donal Carroll, M.C., Dr. Vincent Theodore Carruthers, Dr. Edwin Clark-Jones, Dr. Colin Richard Cole, Dr. Egbert John Connell, Dr. Henry Charles Morriset Delohery, Dr. Joseph Horns Fenn, Dr. James Peter Fitzsimmons, Dr. Andrew Gilmour, Dr. Harry Groom, Dr. John Walter Barron Hannington, Dr. David Heard, Dr. Henry Louis Powell Hulbert, Dr. Reginald Edward Ingram-Johnson, Dr. Spencer Jackson, Dr. Harry Jessop, Dr. Schalk Willem Joubert, Dr. Basil Carlyle Kennedy, Dr. John Timothy Kennedy, Dr. Alfred James Lowe, Dr. Kenneth Alexander Maclean, M.C., Dr. James Macpherson, Dr. Albert George Meares, Dr. Wm. Gardner Neill, Dr. John Oswald, Lt.-Col. Edward Ernest Parkes, R.A.M.C., Dr. Elizabeth Park Young Paterson, Dr. Reginald Spencer Pearson, Dr. Thomas Philip, Dr. Robert Johnson Pirie, Dr. Robert David Prichard, Dr. John Lawson Rankine, Dr. Herbert Midgeley Reeve, Dr. Harry Sautelle Roberts, Dr. Robert Roger, Dr. Robert Rosie, Dr. Jane Buchanan Henderson Ruthven, Dr. Hubert John Satchwell, Dr. Neill Campbell Satt, Dr. Timothy Francis Sheehan, Dr. Francis Wm. Squair, Dr. Vytlingam Supramaniam, Dr. Henry Mortlock Waller, Dr. Sidney Winslow Woollett, O.B.E., Dr. Wm. Alexander Young.	

## DR. J. A. MACDONALD.

158. The Council feels that something more than the ordinary formal notice is due to the memory of Dr. J. A. Macdonald, who for many years not only served the Association with all his strength in many official capacities, but was an outstanding personality who earned the respect and the affection of all who knew him.

## BIRTHDAY HONOURS.

159. The Council has pleasure in reporting that Honours have been conferred upon the following members, to whom the congratulations of the Association have been sent:—

## Companion of Honour.

Prof. J. S. Haldane, F.R.S., Oxford.

## K.C.M.G.

Sir Wm. Thomas Prout, C.M.G., O.B.E., London.

## K.C.V.O.

Prof. John Marnoch, Aberdeen.

## K.B.E.

Major-Gen. W. H. Ogilvie, C.B., C.M.G., K.H.P., I.M.S.

## Knighthood.

Lt.-Col. H. S. Newland, Adelaide.

Dr. T. Watts, M.P., Manchester.

## SIR CHARLES HASTINGS FUND.

160. This Fund was instituted in 1925 by an endowment of about £70 a year due to the generosity of the late Lt.-Col. J. W. F. Rait, I.M.S., and Mrs. Rait. Colonel Rait thought there was room for a fund which could be used promptly and with less formality than the other medical benevolent funds in existence. He particularly wished the Trustees to be able to give at their entire discretion grants or loans to help members of the profession or their dependants in emergency.

The Trustees are the Chairman of the Representative Body, the Chairman of Council and the Medical Secretary. Small grants have been made in a number of cases, mostly in the form of loans, to meet difficulties not likely to recur and which demanded instant action. For example, in several instances loans (without interest and to be repaid when the recipient is in a position to pay) have been made to the sons or daughters of doctors who have died while their children were in the middle of their education. These loans have enabled these very deserving cases to meet class or examination fees. A promising young doctor whose health had broken down was advanced money to enable him to complete a sanatorium course which was benefiting his health but stood in danger of being interrupted for want of funds. These are only a few examples of the uses to which the Fund has been put and the Trustees are glad to feel that the Fund is serving the purpose which its honoured founders had in mind. It is hoped that Colonel Rait's wish may be fulfilled and that other members of the profession may see their way to add to the capital of the Fund, either by donation or bequest.

## GIFT FROM THE NEW ZEALAND BRANCH.

161. Mr. Victor Bonney, the official delegate of the Association at the Annual Meeting of the New Zealand Branch has brought back with him a present which he was asked by the Branch to transmit to the Council. It consists of a handsome inkstand of New Zealand wood, greenstone and silver, and it is inscribed "*Coelum non animus mutant qui trans mare currunt.*"

The Council welcomes this evidence of the loyalty and affection of one of its most distant and most successful Branches and is proud to have this token of kinship to exhibit in the House in proximity to the President's Chair which was the gift of the Australian Branches.

## ANNUAL MEETING, 1930.

162. The Council has approved certain arrangements with respect to the Annual Meeting at Winnipeg, in 1930, and hopes to publish details as to travelling facilities, etc., at an early date.

The Council recommends:—

**Recommendation:** That W. Harvey Smith, M.D., Winnipeg, be elected President of the Association, 1930-31.

## APPOINTMENTS DURING YEAR OF REPRESENTATIVES OF ASSOCIATION ON OUTSIDE BODIES.

(Continuation of para. 24 of Annual Report.)

163. The following further appointments have been made by the Council:—Departmental Committee on Midwives Act, Dr. J. W. Bone; Fourteenth Annual Conference of the National Association for the Prevention of Tuberculosis, the President; 1928 National Conference on Maternity and Child Welfare, Dr. W. Paterson; Advisory Committee of Pharmaceutical Society re Control of Therapeutic Substances, Sir Humphry Rolleston; Court of Governors of University College of South-West England, Mr. Russell Coombe; British Empire Cancer Campaign International Convention, 1928, Mr. R. G. Hogarth and Sir Thomas Horder, Bart.

## NEW SOUTH WALES MEDICAL ROLL OF HONOUR.

164. The Council has been pleased to accept a handsomely bound copy of the New South Wales Medical Roll of Honour, containing the date of appointment to service and the honours, if any, of all members of the medical profession in New South Wales who served overseas. The Roll of Honour may be inspected in the Library of the Association.

## PSYCHO-ANALYSIS COMMITTEE.

165. The Committee appointed by the Council in 1926 to consider, pursuant to the instruction of the A.R.M., the subject of Psycho-Analysis is still considering its reference. Although meetings have been held monthly throughout the session, the work of the Committee is not sufficiently advanced to permit of any report being made at this stage.

## Building.

166. The Council, in view of the great importance of this matter and to ensure continuity in the negotiations and the control of the building operations, has appointed a special Building Committee to consider all questions of rebuilding in connection with the premises of the Association. This special Committee consists of Sir Robert Bolam (Chairman), Dr. H. B. Brackenbury, Mr. N. Bishop Harman, Dr. C. O. Hawthorne, and Dr. R. Wallace Henry, together with the chief officials of the Association acting in an advisory capacity.

## TAVISTOCK SQUARE.

Information was received that Tavistock Square, where the London House of the Association stands, formed part of a Town Planning Scheme under which it was scheduled as residential and not for commercial purposes. Assurance was thereupon sought and obtained that the B.M.A. House was outside the boundaries of the Town Planning Scheme and that, in any case, the Association's building proposals will not be affected.

## DEMOLITION.

Possession was obtained early in September, 1927, of two of the five houses fronting the main road, and the work of demolition was commenced at the earliest possible moment. It was then found that arrangements could conveniently be made for re-housing the two tenants in the other three houses and for proceeding with Blocks A and B together, thus reducing the cost of demolition, excavation and rebuilding. The demolitions have been completed, and the work of excavation is being pushed rapidly forward. It has been found necessary to close the private road leading into the Association's premises, but a covered wooden way has been erected in order to interfere to as small an extent as possible with the convenience of visitors to the premises.

## CONTRACT.

After due enquiry and consideration, the Council approved the erection of Blocks A and B by means of a contract embodying a schedule of agreed prices for work carried out, in lieu of a tender with one price for the complete building. Under such a scheme greater latitude is allowed for alterations which may be found to be necessary or desirable, and no payment is made for work included in the original scheme and subsequently omitted.

## BUILDING LINE.

Very protracted negotiations were necessary with both the Bedford Estate Office and the London County Council over the questions of the front building line and the party walls on the north and south of the proposed extensions. The west side of the main road on which the extension of the B.M.A. House will front had already been settled, and both the Bedford Estate Office and the London County Council, together with the local Borough Council, desired to set out a general building line extending for nearly three-quarters of a mile. Some difficulty was experienced in adjusting the variations in the lines upon which the demolished houses stood. Formal consent from the London County Council has now been obtained to the plan submitted, and the party wall awards setting out the necessary underpinning, position of stanchions, and lighting areas to be left have been duly signed.

## CLERK OF WORKS.

A Clerk of Works of standing and considerable experience has been appointed.

## HOARDINGS.

Consideration was given to the possibility of letting the hoardings fronting the main road to poster advertisers but it was found desirable to utilise the space for announcements concerning the extension of the B.M.A. House, the organisations housed therein, and the prospective tenants.

## SCOTLAND.

A scheme for the extension of the Scottish House of the Association, by the purchase of No. 7, Drumsheugh Gardens, Edinburgh, and the reconstruction of portions of Nos. 6 and 7, Drumsheugh Gardens, has been considered and approved. The work is being carried through; details are given in this report under the heading of "Scotland."

## Organisation.

(Continuation of paras. 47-62 of Annual Report.)

## HONORARY SECRETARIES WHO HAVE RELINQUISHED OFFICE.

167. Since the publication of the last Supplementary Report of Council (B.M.J. Supplement, June 25th, 1927) the following Honorary Secretaries of Divisions and Branches have relinquished office. The Council takes great pleasure in extending to these officers the thanks of the Association, realising as it does that the success of the Association depends very largely upon those who occupy the position of Secretaries of local units of the Association.

## Honorary Secretaries of Divisions.

Division or Branch.	Name of Secretary.	Year of Appointment.
Aberdeen	F. K. Smith	1915

**Medico-Political.****ASSISTANT MEDICAL OFFICERS TO MENTAL HOSPITALS.**

(Continuation of para. 93 of Annual Report of Council.)

168. The Council desires that further time should be allowed during which negotiations may take place with the bodies concerned and considers that it would therefore be appropriate if the Representative Body at the present time confined itself to a general discussion of the proposals contained in Recommendations B to E, leaving over until the A.R.M. 1929 any question of formulation of policy:—

The Council recommends:—

**Recommendation:** That Recommendations B, C, D and E contained in para. 93 of the Annual Report of Council relative to salaries of assistant medical officers to mental hospitals be given general approval, but not made part of the policy of the Association until there has been a further opportunity for negotiations between the Association and the bodies concerned with the appointment of assistant medical officers to mental hospitals:

**ENCROACHMENTS ON THE SPHERE OF PRIVATE PRACTICE.**

(Continuation of para. 91 of Annual Report of Council.)

169. The Special Committee has received a report by the Medical Secretary on the result of his observations with regard to the publicly supplied medical services in several typical areas. This report will be used as the basis of a report which the Council hopes to be able to present to the Divisions in the autumn. In the meantime the Council desires to express its thanks to the Medical Officers of Health in the areas visited, for the generous assistance given to the Medical Secretary during his visits; and also to those Medical Officers who replied so promptly and freely to the requests made to them for particulars of the services in their areas.

**ANTE-NATAL WORK.**

170. The following resolution was passed by the A.R.M. 1927:—

Minute 142.—Resolved: That it be an instruction to the Council to consider the Midwives Act, 1918, in the interests of all concerned with ante-natal work.

As certain of the questions involved in the above reference are being discussed by the Private Practice Committee, and by the Puerperal Morbidity and Mortality Committee, and others will come under the consideration of the Departmental Committee referred to in the next paragraph, the Council considers it inadvisable to present to the Representative Body at the present time any detailed report upon the subject matter of above Minute 142.

A Departmental Committee consisting of Sir Robert Bolam (Chairman), Dr. J. W. Bone, Dame Janet M. Campbell, Lady Cynthia Colville, Dr. W. A. Daley, Mr. J. S. Fairbairn, F.R.C.S., Dr. T. Eustace Hill, Miss Alice Gregory, Mr. A. B. MacLachlan, Dr. F. N. Kay Menzies, Mrs. Bruce Richmond and Miss Stephenson has been appointed with the following reference:—

“To consider the working of the Midwives Acts, 1902 to 1926, with particular reference to the training of midwives (including its relation to the education of medical students in midwifery), and the conditions under which midwives are employed.”

and the Council has authorised the preparation of evidence on the lines of the reference to the Departmental Committee and the nomination of witnesses to give evidence on behalf of the Association before that Committee.

**GENERAL MEDICAL COUNCIL BY-ELECTION, 1928.**

171. In November, 1924, at the election of four Direct Representatives for England and Wales on the General Medical Council the Association's candidates, namely, Sir Robert Bolam, H. B. Brackenbury, J. A. Macdonald, and Sir Jenner Verrall, were returned. The Council regrets to have to report that through the death of Dr. J. A. Macdonald a by-election is imminent. There is also another vacancy caused by the election of Sir Robert Bolam as representative on the General Medical Council for the University of Durham and his consequent resignation of office as a Direct Representative.

The Council has put into operation the following scheme in connection with the two vacancies:—

(1) The Medico-Political Committee shall cause to be circulated as early as possible a notice to every Division in England and Wales (i) advising the Divisions of the fact that an election of two Direct Representatives on the General Medical Council for England and Wales will in the ordinary course take place in October, 1928; (ii) requesting that the Divisions shall call meetings of the whole profession in their areas in order to take this matter into consideration; and (iii) asking to be informed not later than July 2nd, 1928, of the names of any person or persons, legally qualified for election, whom such

meetings may deem suitable to be nominated for election as a Direct Representative.

(2) The Committee shall cause a list to be prepared of those persons, legally qualified for election, who shall have been named in the manner provided in Clause (1). The said list shall be circulated to the Divisions at the earliest possible date before the Annual Representative Meeting, 1928, and each constituency shall be requested to adopt such resolutions as may enable its Representative at the Annual Representative Meeting, 1928, to give effect to the wishes of the constituency in a vote taken in the manner hereinafter prescribed.

(3) At the time of the Annual Representative Meeting, 1928, a Special Meeting of Representatives of Divisions in England and Wales shall be convened, to select from the list of nominees two persons for nomination as Candidates. Voting shall be by ballot. The Candidates who receive the greatest number of votes shall be deemed to be the Candidates selected for support by the Association.

(4) The Medico-Political Committee shall arrange that the persons so selected shall be duly nominated on behalf of the Association as Candidates for the office of Direct Representatives on the General Medical Council, and every effort shall be made by the Association to secure the election of the said Candidates.

**Declaration by Candidate.**

I, the undersigned, hereby consent if duly selected in accordance with the procedure mentioned above, to be nominated as a Candidate at the election in 1928 of two Direct Representatives on the General Medical Council for England and Wales.

Signed .....

Qualifications .....

Address .....

The scheme is with slight variations the same as that approved by the A.R.M. in 1915, the only important exception being that the nomination of Candidates from whom the final selection is to be made at the A.R.M. is by meetings of the whole profession and not by Division meetings.

**INTERNATIONAL MEDICAL SEA CODE.**

(Continuation of para. 92 of Annual Report of Council.)

172. The Council has drawn up a simple questionnaire on the signs and symptoms of disease and injuries for the use of master mariners when seeking medical advice by wireless from a surgeon on another ship or on shore, and has submitted it to the Board of Trade with a request that the Board will assist the Council in its attempt to draw up an international medical sea code by having the questionnaire set into code (or cipher). In order that the code may be of further assistance to master mariners the Council proposes to preface it with explanatory notes and sample messages.

**CHIROPODISTS (REGISTRATION) BILL.**

173. The Chiroprodists (Registration) Bill, introduced into the House of Lords on 2nd May, 1928, by Viscount Novar and down for second reading on 18th July, 1928, has for its object the recognition by the State of chiroprodists as a class of special practitioner. A chiroprodist is defined as:—

“A person who practises chiropody”;

and “Chiropody.”

“means and includes the diagnosis and medical, mechanical or surgical treatment of foot ailments such as abnormal nails, bunions, corns, warts, and callosities, but does not include the performance of operations for which an anæsthetic is required.”

The Council recommends:—

**Recommendation:** That it is undesirable that chiroprodists should be recognised in a special register as such register would convey to the public that chiroprodists were competent to undertake the diagnosis and treatment of diseases of the feet.

**INVESTIGATIONS INTO MATERNAL DEATHS, STILL BIRTHS, NEO-NATAL DEATHS AND PUERPERAL FEVER.**

174. Arising out of suggestions by the Ministry of Health that an investigation should be conducted into all maternal deaths, still births, neo-natal deaths and cases of puerperal fever, the Council decided that such investigations would be useful if carefully controlled by competent experienced medical officers and if the results were used exclusively for scientific and public health purposes, and urged that it was important that, where necessary, such investigation should be followed by the offer of expert advice and assistance, institutional or otherwise. Having received a satisfactory assurance on this matter from the Ministry of Health, the Council (see paragraph 39 of Appendix IV. to the Annual Report of Council, page 168 of the Supplement of 28th April, 1928)

presses upon Divisions and all members of the profession generally, the necessity of giving all the assistance they can towards making the observations under such investigations as complete and accurate as possible. In Circular 888 the Minister of Health has stated that it is his intention to set up a representative Maternal Mortality Committee which will consider the investigations in question, and, with a view to securing uniformity in the methods of obtaining the information desired, he proposes to invite the Committee to draw up a questionnaire to serve as a guide to authorities in making their investigations and hopes that the Committee will commence its work at an early date.

#### REGISTRATION OF NURSING HOMES.

(Continuation of para. 98 of Annual Report of Council.)

175. The Council has approved the draft by-laws which the Ministry of Health proposes to issue to local authorities as a model for the by-laws which these authorities may adopt.

#### MANCHESTER CORPORATION ACT, 1924.

176. Under the Manchester Corporation Act, 1924, a medical practitioner who runs an "establishment for massage or special treatment" (such term including premises used for the reception of persons requiring massage, manicure, chiropody, light, electric, vapour, or other baths, or other similar treatment) may be exempted from registering his house if he lodges with the Corporation a certificate (in the approved form) signed by two medical practitioners practising or residing in the city, not being in partnership with the practitioner concerned or with each other or not having any financial or other interest in the establishment, to the effect that the practitioner concerned is a suitable person to carry on such an establishment. The same position obtains in London under the London County Council General Powers Act, 1915. The Council, while fully recognising the necessity of supervising the activities of persons who are not registered medical practitioners and who are using the above forms of treatment has advised the Manchester Division to point out to the Corporation its objections to the operation of this Act as being a restriction on the legal right of a registered medical practitioner to practise a certain branch of his profession, and to urge that some way be found to remove the restrictions thus placed on medical practitioners.

#### Public Health and Poor Law.

##### APPLICATION TO SCOTLAND OF SCALE OF MINIMUM COMMENCING SALARIES FOR WHOLE-TIME PUBLIC HEALTH APPOINTMENTS.

177. The Annual Representative Meeting, 1927 (Minute 135), approved the action of the Council in agreeing for one year to the following modifications of the scale in its application to Scottish appointments:—

(i) that the commencing salary for resident medical officers be £250 to £400, plus emoluments;

(ii) that the commencing salary of medical officers employed in departments be on a graded scale, the average salary over 10 years being not less than £600, the minimum commencing salary to be not less than £500;

(iii) that the scale of commencing salaries for chief medical officers of health be as follows:—

Population not exceeding 50,000 ...	£800 to £900
" " " 100,000 ...	£900 to £1,100
" " " 250,000 ...	£1,100 to £1,400
" exceeding 250,000 ...	£1,400 to £1,600

(iv) that a minimum commencing salary of not less than £700 may be recognised in county areas, with a population not exceeding 25,000, where co-ordination with an adjoining area is not feasible.

The Council has again given this matter very careful consideration in consultation with the Scottish Committee and the Scottish Branch of the Society of Medical Officers of Health, and has come to the conclusion that under present conditions the scale, as above quoted, offers the best prospect of success in Scotland. As it is understood that the Scottish Board of Health will give no approval of the scale unless it is accepted as a settlement with some assurance of stability the Council recommends:—

**Recommendation:** That the working arrangement—quoted above—agreed to for one year as from 16th June, 1927, with regard to the application to Scotland of the scale of minimum commencing salaries for whole-time public health appointments be extended for a further period of five years on the understanding that if by the end of that period experience shows that the arrangement had not brought about that measure of success in the application of the scale to Scotland which would justify its continuance, the advisability of reverting to the original scale in Scotland be considered.

##### APPLICATION TO NORTHERN IRELAND OF SCALE OF MINIMUM COMMENCING SALARIES FOR WHOLE-TIME PUBLIC HEALTH APPOINTMENTS.

178. So far the scale of minimum commencing salaries has only been applied to England and Wales, and Scotland (in the modified form above-mentioned). At the request of the Ulster Branch, the Council now recommends:—

**Recommendation:** That the scale of minimum commencing salaries for whole-time public health appointments be made applicable to whole-time public health appointments in Northern Ireland.

##### PUPIL ASSISTANTS TO MEDICAL OFFICERS OF HEALTH.

179. During the present session two advertisements were tendered for insertion in the *B.M.J.* inviting applications for pupil assistants to medical officers of health. In one it was stated that the borough council concerned had authorised its medical officer of health to receive one pupil assistant who would live and be boarded at the isolation hospital and that the conditions afforded exceptional training for the D.P.H. The other stated (1) that the Health Committee of the Borough was prepared to receive applications from medical practitioners who desired training in public health administration; (2) that the appointed practitioner would receive instruction in public health administration and be given duties in connection with sanitation, infectious diseases, tuberculosis, bacteriology, maternity and child welfare and school medical work; (3) that there would be ample time for study, classes, etc., and if necessary the certificate in public health administration required for the D.P.H. would be given. The appointment was offered for six or twelve months, no premium being required and no salary offered.

The only declaration by the Association on the subject of pupil assistants for medical officers of health is the following paragraph which appeared in the Supplementary Report of Council for 1909-10, and was approved by the Annual Representative Meeting in 1910:—

37. A question has arisen as to the insertion in the "British Medical Journal" of an advertisement for an Assistant Medical Officer of Health (pupil), from whom a premium was required. The Council is of opinion that it is undesirable that a premium paying pupil of a Medical Officer of Health should in any circumstances be designated "Assistant Medical Officer of Health," and instructions have been given to decline advertisements of the kind.

The Council is of opinion that appointments of this kind should not be advertised in the "British Medical Journal" as it considers it undesirable that persons who are *in statu pupillari* should be engaged in duties which are ordinarily performed by salaried officials.

The Council recommends:—

**Recommendation:** That advertisements for pupil assistants to act (a) either as residents in infectious hospitals, sanatoria or institutions of a similar nature, or (b) to do work usually assigned to assistant medical officers of health or assistant school medical officers, should not be accepted for publication in the "British Medical Journal" whether or not a premium be required.

##### COMBINED APPOINTMENTS OF WHOLE-TIME MEDICAL OFFICER OF HEALTH, POOR-LAW MEDICAL OFFICER AND PUBLIC VACCINATOR.

(Continuation of paras. 119-120 of Annual Report of Council.)

180. In addition to the case referred to in paras. 119-120 of the Annual Report, the Council reports that the Ministry of Health has recently approved a combined appointment of a Medical Officer of Health, Medical Superintendent of Infectious Diseases Hospital, Medical Officer of a Poor Law Institution and District Medical Officer for the Union District and Public Vaccinator on the ground that it must abide by the circular of the Local Government Board of 1910 which definitely encourages such appointments in suitable cases.

##### FEES FOR INSPECTION OF VAGRANTS FOR DIAGNOSIS OF SMALLPOX.

181. In his circular to Boards of Guardians in England and Wales (No. 859, dated 23.1.23) the Minister of Health stated that, in view of the prevalence of smallpox amongst casuals, such persons should be examined by the medical officer with a view to detecting cases of small pox. The circular also stated that "in view of the extra work and responsibility which may be involved by this addition to the medical officer's normal duties the Minister will be prepared to consider any application which may be made by a Board of Guardians for his sanction to the payment of reasonable additional remuneration to the medical officer."

A number of enquiries have been received as to the fee which the Association considers appropriate for poor-law medical officers for this service, and the Council is in negotiation with the Ministry of Health on the matter.

#### PUBLIC EDUCATION IN HEALTH.

(Continuation of para. 116 of Annual Report of Council.)

182. Up to 10th May, 1928, only 31 Divisions and Branches had reported the action they were taking in regard to the education of the public in health matters.

#### STATUS OF MEDICAL OFFICERS OF HEALTH AND TOWN CLERKS.

183. Arising out of correspondence with the Ministry of Health in relation to the status of the M.O.H.s. and Town Clerks the Minister now takes the following position:—

(1) the work of a local authority consists of various elements constituting a whole with reference to which the policy of the authority is framed,

(2) in order to frame that policy, it is necessary for the authority to study these elements in their relations with each other,

(3) to assist it in this process, it requires the services of an officer able to view the work of departments as a whole and to bring them into proper relation with each other,

(4) this officer can be no other than the Clerk to the authority,

(5) the facts stated under the foregoing heads do not, either in principle or in practice, in any way involve the assignment to the Clerk of any functions which properly belong to the Medical Officer of Health or any other professional officer appointed by the Council,

(6) it follows from these facts that official correspondence between the local authority and the Ministry should be conducted, on the side of the authority, through the Clerk, a clear distinction being drawn between such official correspondence and semi-official correspondence between professional officers of the authority and of the department on professional points, whether as a preliminary to the framing of the policy of the Council or otherwise.

The Council had informed the Ministry that it considers it impossible for Town Clerks to be really responsible for the work carried out by Medical Officers of Health and their subordinate medical officers, and that this also applies to the work of all technical officers employed by a local authority. The Council is restating its position in a further letter to the Minister.

#### PUBLIC HEALTH APPOINTMENTS.

184. From 18th June, 1927, up to and including 16th June, 1928, the Association has dealt with matters relating to 206 appointments under the Scale of Minimum Commencing Salaries for Whole-Time Public Health Appointments. In 180 of these the scale salary has either been offered or secured after negotiation, which shows a distinct improvement on the two previous years the figures for which were 1925-26 (first year of operation of scale) 173 appointments dealt with, 138 of which were in accordance with scale; 1926-27, 180 appointments dealt with, 151 of which were in accordance with scale.

#### POOR-LAW APPOINTMENTS.

185. During the session the Association has advised with reference to a number of poor-law medical officer appointments.

#### CO-OPERATION WITH SOCIETY OF M.O.H.

186. During the past session there have been two meetings of the Conference between representatives of the Association and the Society of Medical Officers of Health, at which matters relating to the scale of minimum commencing salaries for whole-time public health appointments have been discussed as well as the question of co-operation between the two bodies.

### National Health Insurance.

#### AMENDING BILL.

(Continuation of para. 127 of Annual Report.)

187. Considerable apprehension has been felt with regard to the possible effect upon the medical profession of the proposals in the new National Health Insurance Bill, at present before Parliament, dealing with additional treatment benefits and their administration. The Third Schedule to the Bill repeals the following Sub-Section 5 of Section 75 of the 1924 Consolidated Act (which was in the original 1911 Act):—

"75. (5) Additional benefits shall be administered by the society or branch of which the persons entitled to the benefits are members, except that where the benefits are in the nature of medical benefit, they shall be administered by and through the insurance committee."

The existence of this section had hitherto been relied upon by the profession as securing that any additional benefits of

the nature of medical benefit should not be administered by approved societies. In order to appreciate the change contemplated under the new Bill, the additional treatment benefits affecting the work of the medical profession are set out in adjoining columns below, as scheduled under the 1924 Consolidated Act and as scheduled under the new Bill.

#### ADDITIONAL BENEFITS.

As scheduled in 1924 Act. As scheduled in new Bill.

1. Medical treatment and attendance for any person dependent upon the labour of a member.

15. Payments to hospitals in respect of the maintenance and treatment therein of members, and the payment of the whole or any part of the travelling expenses incurred by members in travelling to and from the hospital.

17. The payment of the whole or any part of the cost of ophthalmic treatment, other than that provided as part of medical benefit and of the whole or any part of the cost of optical appliances.

20. Such other additional benefits, being of the same character as any of those hereinbefore mentioned, as may be prescribed.

188. An explanatory Memorandum issued by the Ministry of Health pointed out that the additional benefits both previously and as proposed in the new Bill, fell into two classes, namely, those which were of the nature of medical benefit and those which were of the nature of cash payments towards the cost of the provision of treatment. In the first category only one additional benefit was admitted by the Minister to have existed hitherto, namely, medical treatment and attendance on the dependents of insured persons. This particular additional benefit the Bill proposes to abolish, and in these circumstances the Minister pointed out that the necessity for the retention of Section 75 (5) of the 1924 Act no longer existed, whilst on the other hand he would have powers under Clause 14 (3) (7) of the new Bill which would enable him to control the administration of all additional benefits, treatment benefits or otherwise.

189. The Council has always held the view that additional benefits such as ophthalmic benefit, were in the nature of medical treatment, but has had to accept the legal view that they were quite properly administered by approved societies in that they were cash payments by societies on behalf of, or to members. The legal view has been that while in respect of the additional (ophthalmic) benefit an approved society could make these payments towards the cost of the services in question, it could not engage oculists, put them on a panel, and turn its benefit into a free treatment of its members' eyes by these oculists, as such would then be the provision of services or treatment in the nature of medical benefit, within the meaning of above Section 75 (5).

190. If a comparison is made of ophthalmic benefit as scheduled under the old Act, and as now scheduled under No. 13 of the new Bill, it becomes evident that under the new description (the safeguard of Section 75 (5) of the 1924 Act being abolished) approved societies may themselves establish their own clinics for ophthalmic treatment under Clause 13 of the new Schedule and for any other kind of specialist treatment under Clause 16. In this way they might be in a position to select and control staffs, medical and other, and largely to determine the character of the treatment to be carried out. It is true that under the Bill approved societies will be governed by regulations made by the Minister of Health, which the Minister has promised will be submitted to the Association for its consideration prior to their approval. It is conceivable that these regulations would prove acceptable to the profession, but it was considered that the protection hitherto afforded the profession by Section

9. Payments to hospitals in respect of the maintenance and treatment therein of members, and the payment of the whole or any part of the travelling expenses incurred by or in respect of members travelling to and from hospitals.

13. The payment of the whole or any part of the cost of provision of ophthalmic treatment (other than as provided as part of medical benefit) and the whole or any part of the cost of optical appliances.

15. Payments to approved charitable institutions in respect of any treatment of members required for the prevention or cure of disease, not being treatment within the scope of any other additional benefit or of medical benefit.

16. Such other additional benefits, being of a character similar to that of any of those hereinbefore mentioned, as may be prescribed.

75 (5) of the old Act was better than any protection likely to be provided under regulations.

191. Steps were, therefore, taken during the Committee stage of the Bill in the House of Commons to have proposed amendments that the words "the provision of" in additional benefit No. 13 be deleted, that the restricting Sub-Section 75 (5) of the 1924 Act be allowed to stand, or so amended as to maintain the principle that when an additional benefit is of the nature of medical benefit, in whatsoever way it may be administered, it shall not be administered by approved societies. Dr. A. V. Davies, a member of the Standing Committee, kindly undertook to propose these amendments but was not successful, as the Minister declined to accept them.

192. Unsuccessful efforts were made to have the same amendments made to the Bill during the Committee Stage of the House of Lords.

The Bill also proposed an entirely new additional benefit, namely, No. 15:—

"15. Payments to approved charitable institutions in respect of any treatment of members required for the prevention or cure of disease, not being treatment within the scope of any other additional benefit or of medical benefit."

which was considered would prevent a society from making arrangements whereby the services of practitioners in their private capacity could be made available in respect of any treatment of its members required for the prevention or cure of disease (e.g., ear, nose or throat specialists), at private consulting rooms. Consequently, it was suggested to the Minister that the position foreshadowed might be prevented by the insertion after the word "institutions" in additional benefit No. 15, the words "or to registered medical practitioners under a special scheme approved by the Minister for the purpose," which suggestion the Minister intimated his willingness to accept. During the Committee stage in the House of Commons, however, an amendment was tabled for the inclusion of a further additional benefit, namely:—

"The payment of the whole or any part of medical or surgical or specialist services,"

which the Minister had intimated to the proposers he was prepared to accept, and which he informed the Association, with the addition of the words: "Under a special scheme approved by the Minister for the purpose" would seem better adapted to meet the point made by the Association in connection with additional benefit 15. The new suggestion, however, was not considered completely to meet the point of view put to the Minister and it was pointed out that the word "specialist" had not been used in any additional-benefit clause, that it did not appear to have been used in any National Health Insurance Act, and that it was difficult of definition. It was suggested that it would be preferable if the new additional benefit read as follows:—

"The payment of the whole or part of the cost of medical or surgical treatment or advice by any registered medical practitioner not being treatment within the scope of any other additional benefit or of medical benefit under a special scheme approved by the Minister for the purpose."

which suggestion the Minister accepted, and the additional benefit was passed by the Standing Committee of the House in that form. Efforts were made during the Third Reading of the Bill in the House of Lords, to have additional benefit 16 (No. 15 quoted above) so amended that it should not be capable of adoption by an approved society without payments to private medical practitioners for similar advice and treatment at places other than approved charitable institutions being necessarily allowable at the same time. No success, however, attended these efforts.

193. The additional medical treatment benefits as they now appear in the Bill which only awaits Royal Assent are as follows:—

8. The payment of the whole or any part of the cost of medical or surgical advice or treatment by any registered medical practitioner, not being advice or treatment within the scope of any other additional benefit or of medical benefit, under a special scheme approved by the Minister for the purpose.

10. Payments to hospitals in respect of the maintenance and treatment therein of members, and the payment of the whole or any part of the travelling expenses incurred by or in respect of members in travelling to and from hospitals.

14. The payment of the whole or any part of the cost of the provision of ophthalmic treatment (other than as provided as part of medical benefit) and the whole or any part of the cost of optical appliances.

16. Payments to approved charitable institutions in respect of any treatment of members required for the

prevention or cure of disease, not being treatment within the scope of any other additional benefit or of medical benefit.

17. Such other additional benefits, being of a character similar to that of any of those hereinbefore mentioned, as may be prescribed.

194. The Council considers that the failure to secure the retention of Clause 75 (5) of the present Act, or the deletion of the words "the provision of" in additional benefit 13 is regrettable notwithstanding the Ministry's assurance that the position will be amply safeguarded by regulations. If the present or any other Minister should attempt by regulations, or the absence of them, to hand over the administration of benefits of the nature of medical benefit to approved societies it will, of course, be necessary to organise those members of the profession concerned in a refusal to give service under such conditions in pursuance of the well established policy of the Association, and the Council has no doubt that practical unanimity could be got on a point such as this.

The Council recommends:—

**Recommendation:** That it is essential if the medical profession is to take part in the provision of additional (medical) treatment benefits under the National Health Insurance Acts that these, as in the case of statutory medical benefit, shall be administered in such fashion that the services of the medical profession, who elect to give advice and treatment in connection therewith, shall not be under the control of any approved society or societies.

**Recommendation:** That the position set forth in the above resolution should receive statutory recognition and definition.

#### SICKNESS BENEFIT CLAIMS AND MEDICAL CERTIFICATION.

(Continuation of paragraph 126 of the Annual Report.)

195. Discussions are still proceeding between the Insurance Acts Committee and representatives of the Ministry with respect to the above question. Various data dealing with the large increase in the amount of sickness and disablement benefits have been submitted by the Ministry to the Insurance Acts Committee but so far the Committee is not satisfied that the real causes, or at any rate, all of them have been discovered. One thing, however, is plain that the suggestion that the increase is due solely or even mainly to a sudden and radical change in the methods of certification adopted by insurance practitioners as a whole cannot be accepted as a solution.

The Council will give any assistance in its power to ascertain the causes in co-operation with other parties concerned.

#### NATIONAL INSURANCE DEFENCE TRUST.

196. The Insurance Acts Committee submits herewith for the information of the Representative Body and Divisions, a copy of the audited statement for the year 1927, and statement of the income and expenditure accounts for that year, in respect of the National Insurance Defence Trust.

#### Hospitals.

##### CONFERENCE re CONTRIBUTORY SCHEMES FOR HOSPITAL BENEFIT.

(Continuation of para. 137 of Annual Report.)

197. This Conference was held at the offices of the Association on June 6th, under the Chairmanship of the Chairman of Council, and was extremely well attended as is indicated by the following table:—

	No. of Hospitals.	No. of Representatives.
London ... ..	36	58
Provincial ... ..	117	161
Scotland ... ..	5	7
Ireland ... ..	1	1

A very interesting discussion took place upon the Association's memorandum on contributory schemes for hospitals policy and its pamphlet entitled "Policy affecting Hospitals." It was very encouraging to note how the support of the Association's hospital policy by the medical practitioners chiefly concerned has grown since the inauguration of these Conferences in 1920. A full report of the discussion will be found in the B.M.J. Supplement of 16th June, 1928, pages 258-262, copies of which are being circularised to all voluntary hospitals throughout the country.

#### COTTAGE HOSPITALS AND HOSPITAL POLICY.

198. A pamphlet is being prepared dealing with the application of the Association's Hospital Policy to Cottage Hospitals, special reference being made to the method of payment of medical staffs of cottage hospitals for treatment therein.

## CONTRIBUTORY SCHEMES.

199. A model contributory scheme for hospital benefit is in course of preparation, as it is considered that this will be of assistance in securing the adoption of the policy of the Association in regard to such schemes.

## MIDDLE-CLASS HOSPITAL POLICY.

(Continuation of para. 134 of Annual Report of Council.)

200. Consideration of Minute 219 of the A.R.M. 1927 has been deferred until the report of the "Pay Beds Committee" of King Edward's Hospital Fund for London (referred to in para. 132 of Annual Report of Council) is available.

## Naval and Military.

## CONDITIONS OF SERVICE OF THE ROYAL NAVAL MEDICAL SERVICE.

(Continuation of para. 141 of Annual Report.)

201. At the request of a Division, the Council urged upon the Admiralty:—

(a) That there should be an upper limit in the promotion zone, that is to say, an officer after having served for a period of 18 years should be eligible for promotion for a period extending for 5 years beyond that date, and no longer.

(b) That the regulations dealing with the question of pensions should be amended to provide that in no circumstances should the pension of an officer who was in the Service when the 1919 changes were made, and who was retired with the rank of Surgeon-Commander, be reduced below the pre-war figure of £547. 10s. 0d.

In regard to the first question, the Admiralty informed the Council that when promotion to Surgeon-Captain by strict selection was first introduced, it was laid down that there should be no upper limit to the zone of promotion, since otherwise the effect would have been to debar officers very near the top of the Surgeon-Commander's list by seniority from a chance of being selected for promotion; that it considered that the advantages of this system outweighed any possible disadvantages, and that there will always be a certain number of officers who must be aware that they have practically no chance of promotion, and such officers are at liberty, under existing regulations, to apply to retire, if they wish to start a civilian career before reaching the age of 50.

As regards the second question, the Admiralty lays stress on the facts (i) that the 1919 scheme must be viewed as a whole; (ii) that although rank for rank the increase in the rate of retired pay to medical officers was relatively small compared with other Branches, the effect of the new scales was to enable a Surgeon-Commander (entered at, say, the age of 25) to earn the maximum retired pay of his rank after approximately 23 years' service as compared with 30 years' service under the old rules; and (iii) that, under a concession notified in 1922, officers compulsorily retired for age under the new regulations who were on the Surgeon-Commander's list on the 1st July, 1919, will have retired pay of not less than £547. 10s. 0d. per annum assured to them, whatever changes take place in the cost of living.

On the above grounds the Admiralty does not see its way to adopting the Council's suggestions.

The Council has decided to defer further consideration of the question of promotion for 12 months, and as regards pensions the Council has come to the conclusion that no useful purpose will be served by taking any further steps.

## RE-ORGANISATION OF THE MEDICAL SERVICES IN INDIA: THE FUTURE OF THE INDIAN MEDICAL SERVICE.

(Continuation of para. 139 of Annual Report.)

202. There has recently been issued by the India Office a Communiqué concerning the re-organisation of the Medical Services in India to the following effect:—

(i) that the I.M.S. constituted on the same broad lines as at present will be retained primarily to meet the needs of the Indian Army, the Local Governments being required to employ a stated number of I.M.S. officers in order to maintain the necessary minimum war reserve and to provide for European medical attendance for European officers of the I.C.S. and their families;

(ii) that the total number of I.M.S. officers required for civil employment is calculated at 302, of which 212 will be Europeans and 90 Indians;

(iii) that there will be 237 posts for these officers after allowing for leave and study reserve, 178 of which will be in the provinces and 59 under the Government of India.

These posts will be filled as follows:—

Under Provincial Governments: 178 posts, of which 112 must be held by European officers, the remaining 66 to be open to Europeans or Indians.

Under Government of India: 59 posts, of which 28 will be open to Europeans or Indians, the remaining 31 being open to Europeans only;

(iv) that the medical requirements of European members of the Superior Civil Services are based on data which will change from year to year as the proportion of European to Indian officers gradually diminishes and will be subject, therefore, to periodical revision;

(v) that certain rules will come into force as an integral portion of the scheme. These rules deal with the question of employment on the military and civil sides, and provide *inter alia* that liability to serve on either the military or civil side will be a definite condition of service for all future entrants to the Service.

The civil appointments, which are reserved for I.M.S. officers are scheduled, but the Council notes with deep concern that the posts of Chief Administrative Medical Officers of Local Governments are not included in this schedule. In the opinion of the Council this is a retrograde step and is against the best interests of the Service. It means that adequate opportunities are lacking for reaching high rank in the Service, and this, coupled with the fact that employment on the civil side is now so indefinite, renders the new proposals unsatisfactory.

203. After careful consideration of the whole matter, the Council has informed the Secretary of State for India that the Association is convinced that the new proposals will not attract an adequate number of European medical men so long as:—

(a) the posts of Chief Administrative Medical Officers of Local Governments are not specifically included in the list of appointments reserved for officers of the Indian Medical Service; and

(b) the prospect of employment on the civil side, which is the chief inducement to enter the I.M.S. is as indefinite as it is at present.

## Medical Benevolence.

(Continuation of para. 142 of Annual Report.)

## B.M.A. CHARITIES TRUST FUND.

204. From 1st January to 30th April, 1928, the sum of £919 11s. 3d. was received for distribution among medical charities at the discretion of the Trustees (as compared with £809 for the corresponding period last year), and has been distributed as follows:—

	£	s.	d.
Royal Medical Benevolent Fund ...	450	0	0
Royal Medical Foundation of Epsom College ...	400	0	0
Royal Medical Benevolent Fund Guild ...	50	0	0
Sir Charles Hastings Fund ...	49	11	3

In addition, the following amounts have been collected for and transmitted to the undermentioned Funds, the amounts for the corresponding period last year being also given for the purpose of comparison:—

	1928.	1927.
	£ s. d.	£ s. d.
Royal Medical Benevolent Fund	1,107 6 5	1,074 17 7
Royal Medical Foundation of Epsom College ...	756 6 0	749 0 3
Royal Medical Benevolent Fund Society of Ireland ...	34 10 6	22 19 0
Sir Charles Hastings Fund ...	*94 6 2	*56 16 9

\* Includes contributions from the B.M.A. Charities Trust Fund.

## Oversea Branches.

## WINDWARD ISLANDS MEDICAL SERVICE.

(Continuation of para. 144 of Annual Report of Council.)

205. The Medical Registration (Amendment) Ordinance of 1927 will prevent from practising in the Colony unqualified persons and persons not possessed of qualifications which would permit them to be registered in England. This removes a grievance to which the Association has never ceased to call attention since the original ordinance was passed.

The Secretary of the Grenada Branch having reported that the revenue of the Colony showed a substantial increase per head of a growing population and that the annual deficit had been transformed into a surplus which had permitted of the creation of a reserve fund and of steadily increasing expenditure in public services, the Council has informed the Secretary of State that the Association is disappointed to find that the estimates for the Colony for 1928 make no provision either for an improvement of the scale of salaries of the medical officers or for an increase in the medical establishment. In doing so the Council has called attention to statements by the Secretary of State and statements contained in reports dealing with the Service, which indicated that improvement

in the scale of salaries and increase in establishment should receive attention at the earliest possible moment. A copy of this letter has been forwarded by the Colonial Office to the Governor of the Windward Islands.

#### DELETERIOUS DRUGS ORDINANCE OF STRAITS SETTLEMENTS.

(Continuation of para. 145 of Annual Report of Council.)

206. According to a local newspaper it appears that the regulations under the Deleterious Drugs Enactment (Federated Malay States and Straits Settlements) have been brought into line with the Dangerous Drugs Regulations of the United Kingdom, but official confirmation of this has not yet been received.

#### INDIGENOUS SYSTEMS OF MEDICINE IN CEYLON.

207. The Colonial Office has reported that the Legislative Council of Ceylon has made provision in its estimates for 1927-28 for the sum of Rs.75,000 as a grant for Ayurvedic study.

#### WORK OF THE OVERSEA BRANCHES.

208. The reports of the Australian Federal Committee, of the Federal Council in South Africa, and of practically the whole of the Branches of the Association overseas show a splendid record of activity. The following points are of special interest.

#### AFRICA.

##### The Union of South Africa.

209. The outstanding event of the year has, of course, been the First Annual Scientific Meeting of the Medical Association of South Africa (British Medical Association), held in Bloemfontein. This was attended by the Chairman of the Council of the Association and other home delegates who have reported most enthusiastically on the success of the Congress and the kindness that was shown to them. The Council offers its hearty congratulations to the President of the Congress, Dr. C. H. Bidwell, the Honorary Secretaries, Drs. Alice Cox, Marion Thomson, and Louise Tomory, and the members of the Orange Free State Branch who did so much to secure the success of the Congress. The Federal Council under the Chairmanship of Dr. A. J. Orenstein has been engaged during the year in many matters of the greatest importance to the profession in South Africa. It has been particularly active in placing the organisation of the Branches on a satisfactory footing, many new Divisions have been formed, and the membership has consequently increased considerably. The logical outcome of its action in this connection is a proposal to amend the constitution by creating a House of Delegates which would occupy a position similar in status to that of the Representative Body in this country. The suggestion has wisely been postponed for the time being until the new Constitution has been further tested. The questions of the payment of medical staffs of public hospitals, the training of native medical assistants and the proposed National Insurance Scheme for South Africa are engaging the attention of the Federal Council and are of the first importance. The Council is glad to note that in addition to the great activity shown by the Federal Committee and the Branches in the ordinary work of the Association, the Association in South Africa has during the year increased its Benevolent Fund from £400 to £1,000.

##### South-West Africa.

210. The South-West Africa Branch which works under conditions of distance, climate and travelling difficulties that make organisation extremely difficult, has been successful in securing the extension of the provisions of the Union Medical, Dental and Pharmacy Bill to South-West Africa, and, as a result of this, the unsatisfactory position with regard to the control of medical and pharmacy matters which has existed since the end of the German occupation has been settled.

##### Rhodesia.

211. The Mashonaland Branch is in a flourishing condition and reports a regular series of monthly meetings.

##### East and West Africa.

212. The Kenya and Sierra Leone Branches report a year of successful activities and increased memberships, the former body having held no less than 11 meetings. Practically all the doctors in these areas are members of the Association.

#### ASIA.

##### India.

213. The Bombay Branch has approved a report on the question of registration of midwives in the Presidency. The Branch has also under consideration the question of free and paying treatment in public hospitals, and with its record of activity it is not surprising to find that the Branch membership is steadily increasing.

A new Calcutta Branch has been formed during the year, and there is every indication that the new body will meet a long felt want in the area. The thanks of the Council are given to those members who have made this fresh start in circumstances of great difficulty.

The incidence of tuberculosis in Hyderabad has engaged the serious attention of the Branch there, and a scheme has

been drawn up for the construction of a tuberculosis sanatorium. The Branch has made application to the Government for a grant towards the cost of the Institution, and the remainder of the money required will be raised by voluntary contributions.

The need for a medical organisation has long been felt in the Punjab, and to meet this need the Punjab Branch has recently been revived. Forty-five new members have joined the Branch and a fine programme of scientific meetings at frequent intervals was carried through.

The South Indian and Madras Branch also reports a year of successful activity.

#### Ceylon.

214. The action taken by the Ceylon Branch in connection with the question of indigenous systems of medicine in Ceylon is dealt with in the Council's Annual Report. A record of nine meetings with an increased membership completes a satisfactory year's work.

#### Hong Kong and China.

215. Notwithstanding the unsettled conditions in China, the Hong Kong and China Branch has been active during the year, and a most successful function was recently held at which over 100 medical practitioners were present.

#### Malaya.

216. The Malaya Branch has now its own medical journal which is the official organ of the Branch. The Branch has considered questions relating to the Malayan Medical Service and to the deleterious drugs ordinances of the Straits Settlements. Its membership is now nearly 300, which represents a considerable increase during the year.

#### AUSTRALASIA.

217. The membership of the Association in Australasia is now over 5,000, representing a remarkable increase of over 1,200 in the past five years. The Branches of the Association in Australasia severally and collectively are in an enviable position both as regards numerical strength and influence.

#### Australia.

218. The Australian Federal Committee under the Chairmanship of Sir George Syme has again had before it many matters of importance to the profession in the Commonwealth. The Council is greatly interested to note that the Federal Committee, after considering the question of medical service in public hospitals, has reached the conclusion that in public hospitals which treat as in-patients those who are able to pay in whole or part the cost of maintenance and treatment, the medical staffs should receive payment for their services to those who pay while continuing to treat gratuitously those unable to pay. The Committee discussed with the Australian Pharmaceutical Conference points of mutual interest in connection with the proposed national health insurance scheme. Other matters dealt with include the adoption of a Common Form of Agreement for the use of the whole of the Branches in Australia in connection with Friendly Society Lodge Practice; the drafting of model rules governing procedure in ethical matters; and the adoption of uniform rates for travelling medical officers of life assurance societies.

The membership of the New South Wales Branch again shows a satisfactory increase. No less than 20 meetings were held during the year, the ordinary meetings being arranged with meetings of clinical sections, a system which has been found to work very satisfactorily. Additional land has been acquired for the new premises of the Branch, and the system of B.M.A. Lectures delivered at meetings of local associations outside the metropolitan area has been continued. In connection with the holding of the third Session of the Australian Medical Congress in Sydney in 1929, Sir Alexander MacCormick has been appointed President by the Federal Committee, and the organisation of the Congress is proceeding satisfactorily.

The organisation of the Queensland Branch has been improved by the formation of nine local medical associations during the year. Conference of representatives of country local medical associations and of the Bush Nursing Association have been held for the consideration of the hospital policy of the Branch. The Branch contemplates obtaining new premises, and the questions of finance and a suitable site are now under consideration. A successful post-graduate course lasting over several days, and the formulation, in co-operation with the City Medical Officer of Health, of a scheme of diphtheria immunisation, complete a satisfactory year's work.

The Victorian Branch reports 21 meetings and an increased membership. The report of the Branch for the year covers a wide field of great interest and importance to the profession in Victoria. Numerous ethical problems have again been dealt with; the formation of a Lodge Medical Practitioners' Section of the Branch has been approved, and action has been taken in connection with the salaries of municipal health officers, state medical officers, and resident medical

officers of public hospitals, in the majority of cases with satisfactory results. Owing to the growing importance of the hospital policy of the Association a special Hospitals Committee has been formed to deal with all matters in connection with hospitals. The Medical Agency under the auspices of the Branch continues in a flourishing condition, as does also this British Medical Insurance Company.

The work of the Council of the Western Australian Branch has been particularly heavy during the year. The new provisions of the Workers' Compensation Act having entailed careful consideration.

#### Tasmania.

219. The Tasmanian Branch reports an improvement in the amount of clinical work that has taken place at meetings of the Branch. The post-graduate work of the Branch has been continued and several important ethical questions have been decided.

#### New Zealand.

220. The New Zealand Branch reports an increase of 45 in its membership. During the year, the Branch took steps for its Incorporation, and the Council extends to the Branch its best wishes for continued success under the new regime under which the corporate status of the Branch will be improved. The Branch has now received, from Dr. MacEachern, who, in 1926, made a tour of the hospitals in New Zealand at the request of the Branch, a comprehensive report on the whole situation. The report will be a valuable source of reference and the Branch is in communication with the Government with a view to publication and circulation of the report.

The Executive Committee of the Branch has been in frequent communication with the Government on matters bearing on the health of the community; the newly-formed Obstetrical Society, which aims at enrolling all members of the Association in New Zealand actively engaged in obstetrical work, has been affiliated to the Branch; the Medical Agency, the net profits of which belong to the members of the Branch continues to fulfil its useful purpose, and the Medical Benevolent Fund has now reached the satisfactory total of nearly £7,000.

#### WEST INDIES.

221. The Jamaica Branch, the oldest of the Overseas Branches of the Association celebrated its Jubilee in December. The Council, on behalf of the whole membership of the Association, extends to the Branch hearty thanks for past good work, congratulations on the jubilee and best wishes for increasing usefulness of the Branch to the profession in Jamaica.

H. B. BRACKENBURY, Chairman.

#### British Medical Association.

##### CURRENT NOTES.

##### Spa Practitioners Group: Annual Conference.

THE attention of members of the Spa Practitioners Group of the Association is drawn to the fact that the first annual conference of this Group will be held during the course of the Annual Meeting at Cardiff on Wednesday, July 25th, at 2.30 p.m.. Every member of the Association who regularly prescribes the mineral waters or baths of the spa in which he resides, or who is on the staff of a hospital or clinic where the use of local mineral waters is part of the routine treatment is *ipso facto* a member of the Group.

##### Consulting Pathologists Group of B.M.A.: Annual Conference.

The first annual conference of the Consulting Pathologists Group will be held at Cardiff on Wednesday, July 25th, at 4.30 p.m., upon the conclusion of the Spa Practitioners Group Conference (referred to above). Every member of the Association (not being a member of the Public Health Service) who is working in an institution or private pathological laboratory engaged in examining and reporting on specimens for clinical purposes is *ipso facto* a member of the Group.

#### Association Notices.

##### EAST YORKS AND NORTH Lincs BRANCH: EAST YORKSHIRE DIVISION.

NOTICE is hereby given by the Council to all concerned that the East York and North Lincoln Branch and the East York Division of that Branch, respectively, propose that their names be altered to East Yorks and North Lincs Branch, and East Yorkshire Division. Any body or person affected by either of these proposals, and objecting thereto, is requested to notify the Medical Secretary, stating reasons, by not later than July 30th.

## TABLE OF DATES.

July 25, Wed.	Council, Cardiff. Conference of Honorary Secretaries, Cardiff.
July 26, Thurs.	Meetings of Sections, etc., Cardiff.
July 27, Fri.	Meetings of Sections, etc., Cardiff.

ALFRED COX, Medical Secretary.

## BRANCH AND DIVISION MEETINGS TO BE HELD.

**DORSET AND WEST HANTS BRANCH.**—The summer meeting of the Dorset and West Hants Branch will be held at the Church House Hall, Wimborne, on Wednesday, July 4th, at 3 p.m., when Mr. Rooke, president, will take the chair. Agenda: Communications; time and place of next meeting. Papers:—Dr. Whitaker: "Historical theories of the cardio-vascular system"; Dr. Luker: "Haemorrhage in early pregnancy." Lunch (price 2s. 6d.) can be obtained at the King's Head Hotel. Dr. Le Fleming invites visiting members to tea at his house after the meeting.

**DORSET AND WEST HANTS BRANCH: BOURNEMOUTH DIVISION.**—The annual social meeting of the Bournemouth Division will be held on Saturday, July 14th, when a visit will be paid to the Pitt Rivers Museum, Farnham, Blandford, to be followed by tea at Larua Tree Grounds, Tolland Royal.

**EAST YORKS AND NORTH LINCOLN BRANCH.**—The seventy-second annual meeting of the East Yorks and North Lincoln Branch will be held at Driffield on Wednesday, July 18th, at 1.15 p.m. Business: Amended draft by-laws; annual report and financial statement for 1927; election of officers for 1928-29. The president (Dr. Erc) will introduce the new president (Dr. Nelson), who will then take the chair. Luncheon will be served at the Bell Hotel at 1.30 p.m., after which he will deliver his introductory address. An excursion is being arranged to some place of interest in the neighbourhood. The president and Mrs. Nelson kindly invite members and their wives to afternoon tea in the hotel at 4.45.

**LANCASHIRE AND CHESHIRE BRANCH: SOUTHPORT DIVISION.**—A meeting of the Southport Division will be held at 52, Hoghton Street, Southport, to-day (Friday, June 29th), at 8.30 p.m. The main business is to discuss the Annual Report of Council. It is hoped that every member will make an effort to be present.

**METROPOLITAN COUNTIES BRANCH: HENDON DIVISION.**—The next meeting of the Hendon Division will be held at Hendon Cottage Hospital to-day (Friday, June 29th), at 8.30 p.m. Agenda: Clinical meeting, cases and specimens will be shown by Drs. B. B. Morley, J. W. Ensor, R. Hunt Cooke, and Mr. L. G. Phillips; consideration of Supplementary Report. Dr. and Mrs. H. R. S. Walford have extended an invitation to members of the Division and their friends to view, from their grounds at Hendon Grove, the Air Pageant on Saturday, June 30th, at 2.30 p.m.

**METROPOLITAN COUNTIES BRANCH: ST. PANCRA'S DIVISION.**—A meeting of the St. Pancras Division will be held at the British Medical Association House, Tavistock Square, W.C.1, on Tuesday, July 10th, at 9 p.m. Dr. W. Camae Wilkinson will read a paper on the home treatment of tuberculosis by the general practitioner.

**METROPOLITAN COUNTIES BRANCH: WANDSWORTH DIVISION.**—The second meeting of the Wandsworth Division to consider the Koch diagnosis and treatment of tuberculosis by means of tuberculin, together with a proposal for a collective investigation into the subject, will be held in the Town Hall, Wandsworth, to-day (Friday, June 29th), at 9 p.m. Dr. Carswell will read a paper entitled "Treatment, and a proposal for a collective investigation." The meeting will be open to all members of the medical profession.

**NORFOLK BRANCH.**—The annual meeting of the Norfolk Branch will be held at the Town Hall, Aylsham, on Thursday, July 5th, at 3 p.m. Agenda: Report of the Branch Council and annual financial statement; induction of the new president, Dr. B. E. Sapwell, by the retiring president, Sir Hamilton Ballance, K.B.E., C.B.; election of officers; an address by Mr. Vivian Carter, British secretary of Rotary International, on the diagnosis of personality. Tea (to which ladies are invited) at 4.30 p.m. at the Grange, Aylsham, by invitation of Dr. Sapwell and Miss Sapwell.

**NORTHERN COUNTIES OF SCOTLAND BRANCH.**—The annual meeting of the Northern Counties of Scotland Branch will be held at the Station Hotel, Kyle of Lochalsh, on Saturday, June 30th, at 2.5 p.m. Business: Report of election of officers of Branch; report of Branch Council and annual financial statement. Before the meeting members and their guests will lunch together at the hotel at 12.30 p.m. After the meeting there will be an opportunity for those who wish to play golf, and motor boat cruises are also being arranged. For members coming by road who do not wish to take their cars across Dornie Ferry, motor transport will be arranged from there to Kyleakin, leaving the west side of the ferry at 11.45 a.m.

**NORTHERN COUNTIES OF SCOTLAND BRANCH: ISLANDS DIVISION.**—The general meeting of the Islands Division will be held on Saturday, June 30th, in the Station Hotel, Kyle of Lochalsh, at 10.30 a.m., to elect officers and Executive Committee.

**NORTH LANCASHIRE AND SOUTH WESTMORLAND BRANCH.**—The annual meeting of the North Lancashire and South Westmorland Branch will be held on Tuesday, July 3rd, at 3.15 p.m., in the Ethel Hedley Hospital, Calgarth (by kind permission of Dr. Hough and the Governors of the Hospital). Dr. J. Lang Cochrane will deliver his presidential address. Ladies are invited, and a boat on Lake Windermere will be placed at their disposal.

**NORTH WALES BRANCH.**—The annual meeting of the North Wales Branch will be held at the North Wales Sanatorium, Llangwffan, Denbigh, on Friday, July 6th. The council of the Welsh National Memorial Association and the house committee of the sanatorium will entertain the members to lunch, and a tour of the institution will be made. Agenda and further particulars will be announced later, but members are requested to make a note of the date as a large attendance is hoped for.

**SOUTH MIDLAND BRANCH: BEDFORDSHIRE DIVISION.**—The annual meeting of the Bedfordshire Division will be held at the Swan Hotel, Bedford, on Wednesday, July 4th, at 3 p.m. Agenda: Annual report for 1927; election of officers; Supplementary Report of Council; address by Sir Maurice Craig entitled "Some points in the treatment of nerve exhaustion." Tea will be provided. The chairman invites the members to luncheon at the Swan Hotel at 1.15 p.m. An Executive Committee meeting will be held at 2.30.

**SURREY BRANCH: CROYDON DIVISION.**—A general meeting of the Croydon Division will be held at the Croydon General Hospital on Tuesday, July 3rd. Dr. G. E. E. Brayne-Nicholls will take the chair at 8.30 p.m. Agenda: Correspondence; formation of Charities Committee; to instruct representatives in Representative Body.

**YORKSHIRE BRANCH: SHEFFIELD DIVISION.**—The Executive Committee of the Sheffield Division have decided to welcome the successful students at the final M.B. examination, including those who have qualified since June, 1926, at a luncheon to be held at the Royal Victoria Hotel, Sheffield, on Wednesday, July 4th, at 1.15 p.m. The luncheon is open to all members of the Sheffield Division. Tickets, 6s. each (without wine). A general meeting will be held at the Church House, St. James Street, Sheffield, on Friday, July 6th, at 8.30 p.m. Agenda: Annual Report of Council and instruction of representatives. It is hoped that there will be a large attendance.

## Meetings of Branches and Divisions.

## BOMBAY BRANCH.

The annual meeting of the Bombay Branch was held on May 23rd at the Pathological Laboratory of the Grant Medical College, when Dr. Row was in the chair. At the outset Dr. Row referred in feeling terms to the great loss sustained by the medical profession and the Bombay Branch by the untimely death of Dr. A. K. Contractor, and a resolution of condolence was adopted.

The meeting considered the rules regarding eligibility as representative of the Branch to the Annual Meeting of the British Medical Association. Draft rules submitted by the Branch Council for guidance in electing a representative to the Annual Meeting were approved as suggestions.

Dr. NUNAN, at present in England, was unanimously elected as representative in the Representative Body.

The SECRETARY having read the annual report, Dr. Row traced the history of the resuscitation of the Branch about two years ago. He thanked his colleagues, especially the secretaries, Drs. Yodh and Bana, who, he said, had carried on the work under great difficulties. The report was unanimously adopted, as were also the accounts.

The following officers were elected for the year 1928-29: President, Lieut.-Colonel A. F. Hamilton, I.M.S. Vice-Presidents, Major S. K. Engineer, O.B.E., and Dr. J. E. Sandilands, M.C. Joint Honorary Secretaries and Treasurers, Dr. F. D. Bana and Dr. B. B. Yodh.

Colonel HAMILTON, having been inducted in the chair, thanked the members for electing him as president, and a vote of thanks to the retiring president was passed unanimously.

NOTICES OF MOTION BY DIVISIONS FOR THE  
ANNUAL REPRESENTATIVE MEETING,  
CARDIFF, 1928.

## Scheme for Co-ordination of Hospital Provision.

By CAMBERWELL: That (with reference to the recommendation contained in para. 135 of the Annual Report of Council) the "scheme for co-ordination of hospital provision" reported in Appendix VII, in as far as it concerns the public hospital, be referred back to the Council for further consideration.

## Secret Remedies.

By LANCASHIRE AND CHESHIRE: That the Representative Body instruct the Council to consider the advisability of resuming the investigation into the composition of secret remedies and the publication of the results.

## Pathological Reports.

By SOUTH STAFFORDSHIRE: That subpara. (3) of the recommendation contained in para. 117 of the Annual Report of Council be amended by the addition of the words "and where no hospital facilities exist for the provision of pathological investigations for such patients" after the words "pay a fee."

WEST LONDON HOSPITAL, Hammersmith Road, W.6.—Resident Assistant Surgeon. Salary £200 per annum.

WORKING AND DISTRICT VICTORIA HOSPITAL.—Orthopaedic Surgeon.

WORTHING HOSPITAL.—House-Surgeon (male). Salary at the rate of £150 per annum.

WOOLWICH UNION.—Second Assistant Medical Officer at the Plumstead and District Hospital (male, unmarried). Salary £350, rising to £400.

WREXHAM AND EAST DENBIGHSHIRE WAR MEMORIAL HOSPITAL.—Two Resident House-Surgeons (male). Salary at the rate of £100 per annum each.

YORK: THE RETREAT.—Temporary Assistant Physician (male). Salary six guineas weekly.

MEDICAL REFERRITS UNDER THE WORKMEN'S COMPENSATION ACT, 1925, for (1) the Inverness (Midland) District, and (2) the Wick District. Applications to the Private Secretary, Scottish Office, Whitehall, S.W.1. by July 10th.

This list of vacancies is compiled from our advertisement columns, where full particulars will be found. To ensure notice in this column advertisements must be received not later than the first post on Tuesday morning.

## DIARY OF SOCIETIES AND LECTURES.

ROYAL SOCIETY OF MEDICINE.  
Annual General Meeting.—Tues., 4 p.m.  
General Meeting of Fellows.—Tues., 5.20 p.m.

HARVEY SOCIETY, Guy's Hospital, S.E.—Thurs., 4.30 p.m., Demonstrations in the Cardiological, Bacteriological, and X-Ray Departments.  
MEDICO-LEGAL SOCIETY, 11, Chandos Street, W.1.—Thurs., 8.30 p.m., Annual General Meeting, followed by ordinary meeting. Mr. Noel Middleton: Testamentary Capacity.

## POST-GRADUATE COURSES AND LECTURES.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—*Brookley Hill Country Orthopaedic Hospital*: Demonstration, Tues., 11.30 p.m., if ten post-graduates notify their intention to be present (telephone Mayfair 2246); no fee. *Royal Westminster Ophthalmic Hospital*, Broad Street, W.C.2: Demonstration, Thurs., 3 p.m.; no fee. *Charing Cross Hospital*, W.C.2: Demonstration, Fri., 2 p.m.; no fee. *West End Hospital for Nervous Diseases*, Welbeck Street, W.: Special Course of Lectures and Clinical Demonstrations upon selected cases at 5 p.m. daily. Tickets from the Fellowship of Medicine, 1, Wimpole Street, W.1.  
NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.15.—Mon., 2.30 to 5 p.m., Medical, Surgical, and Gynaecological Clinics; Operations. Tues., 2.30 to 5 p.m., Medical, Surgical, Throat, Nose, and Ear Clinics; Operations. Wed., 2.30 to 5 p.m., Medical, Skin, and Eye Clinics; Operations. Thurs., 11.30 a.m., Dental Clinics; 2.30 to 5 p.m., Medical, Surgical, and Ear, Nose, and Throat Clinics; Operations. Fri., 10.30 a.m., Throat, Nose, and Ear Clinics; 2.30 to 5 p.m., Surgical, Medical, and Children's Diseases Clinics; Operations.

ST. PAUL'S HOSPITAL, Endell Street, W.C.2.—Thurs., 4.30 p.m., Hydro-nephrosis.

JOINT TUBERCULOSIS COUNCIL.—Special Course at Cambridge, Mon. to Sat.

LIVERPOOL UNIVERSITY CLINICAL SCHOOL. ANAT-OMICAL CLINICS.—Royal Infirmary: Mon. and Thurs., 10.30 a.m. Maternity Hospital: Mon. Tues., Wed., Thurs., and Fri., 11.30 a.m.

# INDEX TO THE EPITOME FOR VOLUME I, 1928.

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma; Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocoele, Goitre, and Thyroid; Diabetes, Glycosuria, and Sugar; Eye, Ophthalmia, and Vision, etc.

The Figures in this Index refer to the Number of the Paragraph, NOT the Page.

- A.
- Abdominal adhesions and prevention of post-operative peritonitis, 41
- Abdominal surgery, temporary haemostasis in, 412
- Abdominal wall, cystic swellings of, following trauma, 453
- Abortion followed by genito-peritoneal tuberculosis, 199
- Abortion, induced, late sequelae of, 493
- Abscess, amoebic, emetico in, 570
- Abscess of liver, treatment of, 59
- Abscess, perforo-sellar, 57
- Abscess, peritoneal, following tonsillectomy, 6
- Abscess, pulmonary, and gangrene, surgical treatment of, 352
- Abscess of spleen in typhoid fever, 138
- Accidents followed by extrapyramidal symptoms, 269
- "A.C.E." anaesthetic mixture, a modified (alkoform), 257
- Acetabulum, fractures of the, 537
- Acetone treatment of cancer of the cervix, 127
- Acid-fast bacilli. See Bacilli
- Acidosis in athletes, 268
- Acidosis, diabetic, 405—Chemical changes concerned in, 661
- Acrodermatitis perstans, 304
- Acron, H. W.: Etiology and treatment of (porokeratosis), 122
- ADAMANTIAPIS, B.: Keratitis due to an infection of trachoma, 523
- ADAMS, D. R.: Cutaneous spirochaetosis due to *Treponema cuniculi* in British rabbits, 553
- ANDERSON, W. L. T.: Saline solutions in hypertension, 490
- Adenomas of rectum, carcinomatous degeneration in, 60
- ADLER, K.: Fracture of the clavicle during spontaneous labour, 501
- Adrenaline, effects of on respiration, 642
- Agitation, states of, somnific in, 65
- Air embolism, death from, 457
- Alcohol in acute infectious diseases, 489
- ALLEN, E. V.: Thrombo-angitis obliterans, 295
- ALOR, V.: Tuberculosis of the breast, 214
- ALVAREZ, W. C.: Intestinal absorption, 308
- Amate bodies in scarlet fever, 130
- Amaurotic constant, 521
- Ambard's constant and the renal functions, 333
- Amenorrhoea, extensive pigmentation of the skin associated with, 124—Treatment of, 549
- Amino bases of ergot, 223
- Amoebic abscess. See Abscess
- Anaemia, pernicious: Liver feeding in, 144, 170, 343, 344, 353, 513—Etiology of, 284—In pregnancy, 353
- Anaerobic bacteriaemia, 635
- Anaesthesia, ether, carbon dioxide administration during, 577
- Anaesthesia, ethylene, 578
- Anaesthesia in gall-bladder surgery, 13
- Anaesthesia, rectal, 12—Ether and gas-oxygen, 255
- Anaesthesia, regional, for operations on the spinal column, 14, 452
- Anaesthesia, sacral block, 575, 576
- Anaesthesia, spinal, in obstetrics, 201—In labour, 375—Ocular complications of, 450
- Anaesthesia, solachnic, in upper abdominal operations, 451
- Anaesthetic mixture, a modified "A.C.E." (alkoform), 257
- Anaesthetic properties of hedonal, 256
- Anaesthetist in certain surgical emergencies, 11
- Analgic preparation (Chalgine), 255
- Anaphylaxis, bacterial, the nature of, 456
- ANDERSON, J.: Prognosis in abdominal pregnancy, 125
- ANDERSON, M. S.: Treatment of pulmonary tuberculosis by sanocrysin, 518
- ANDERSON, W. D.: Eobedrine hydrochloride in n, 91—In ology of, 276
- Antirax, local immunization against, 263
- Antihodies, typhoid and dysentery, in mental patients, 43
- Anti-gangrene serum in treatment of typhoid fever, 143
- Antistreptococcal serum in treatment of puerperal septicemia, 525
- Antitoxic action of yeast extract, 540
- Antitoxin treatment of scarlet fever, 252
- Anuria, post-operative, boric glycerin injections in, 571
- Aortic syphilis. See Syphilis
- Aplasia, bilateral ovarian, 259
- Appendicitis: Stimulated by ovarian haemorrhage, 162—Post operative complications of, 216—Serum treatment of, 574
- Appendicitis, acute, 539; and cyclical vomiting in children, 464
- Appendicitis, chronic, 487
- Appendix, spontaneous amputation of, 87
- Aqueous humour, transmission of arsenic to the, 519
- ARMSTRONG, C.: Tetanus caused by skin dressings, 339
- Arsenic and bismuth therapy in Hodgkin's disease, 448
- Arsenic, passage of into the cerebrospinal fluid, 641
- Arsenic in syphilitic aneurysms, 275
- Arsenic, transmission of to the aqueous humour, 519
- Arterial spasm and occlusion of branches of the retinal artery, 68
- Artery, retinal, bilateral pre-papillary vascular loop of, 69
- Asphyxia, localized, due to cold, 559
- Asphyxia neonatorum, 633
- Asthma, intrabronchial medication in, 32—In childhood, 36—Skin affections in, 123, 302—Radiotherapy in, 173, 471, 472—Treatment of, 370—X-ray treatment of, 471, 472—Ephedrine in, 517
- Asthma, bronchial, treatment of, 300
- Asthmatic patients, diphtheria prophylaxis in, 289
- Ataxia, Friedreich's, 280
- Athletes, acidosis in, 268
- Atrophy, optic, hereditary and familial, 67
- AVOER, L.: Death from air embolism, 457
- AVICCHIO, V.: Value of the Dick reaction, 27
- Auricular fibrillation in an apparently normal heart, 133
- Auricular fibrillation, chronic, treatment of, 322
- Autohaemotherapy in spasmodic coryza, 254—In conjunctivitis, 494
- Autonomic system, action of ergotamine on the, 525
- AYMAN, D.: Sublingual absorption of drugs, 492
- AYRES, K. D.: Death in acute intestinal obstruction, 446
- AZA, V.: Genito-peritoneal tuberculosis following abortion, 199
- B.
- BAAGÖE, K. H.: Skin affections in asthma, 123, 302
- Bacilli, acid-fast, resistance of to oil emulsion, 44
- Bacilli isolated from rhinoscleroma, serological classification of, 106
- B. aertrycke* infection of animals killed in slaughterhouses, 46
- B.O.G. vaccine, modification of tuberculous lesions by, 79
- Bacillus of diphtheria, virulence of, 262
- B. paratyphosus* A isolated from the pig, 104
- B. perfringens* causing puerperal septicemia, 72
- Bacillus, tubercle: The filterable elements of, 236—Resistance of to putrefaction, 504—Bacteriolysis of, 354—Filterable forms of, 480
- Bacillus typhosus*: Precipitable substances derived from, 179—Thin H- and O-forms of, 637
- BACQUELAINE: Treatment of cholecystitis, 317
- Bacteria, common, culture of filterable forms of, 19
- Bacteria in spinal fluids, 584
- Bacteremia, anaerobic, 605
- Bacterial anaphylaxis, the nature of, 456
- Bacterial cultivation, the exhaustion of media in, 42
- Bacterial flora of periapical infections, 381
- BADOUX, V. E.: Sero-diagnostic methods in tuberculosis, 555
- BAER, W.: Bilateral ovarian aplasia, 259

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 1. Etiology of Migraine.

J. S. DIAMOND (*Amer. Journ. Med. Sci.*, November, 1927, p. 695) enumerates the various views that have been held as to the causation of migraine, and states that no scientific data have ever been collected to indicate a definite lesion or cause. The belief that the liver is responsible for this ailment has been long held, and the introduction and established utility of liver function tests have enabled the testing of its validity. Diamond performed a series of tests on 35 carefully chosen patients, cases in which other pathological processes were found and cases of symptomatic migraine being excluded. Of these patients 21 were female and 14 male; their ages ranged from 19 to 46. In over two-thirds there was a history of onset in the first and second decade, the remainder being in the third. Nearly all gave a familial history, the transmission being usually through the mother. The frequency of attacks varied from four to six weeks to once or twice a week. Headache of hemispherical type was present in all the cases, which were placed in three groups: in Group A (12 cases) the headache was of purely cephalic type without digestion upset; in Group B (15 cases) it was associated with nausea and vomiting, the so-called bilious attack; and in Group C (8 cases) the gastric and abdominal symptoms predominated. Complete examinations were made in each case, the tests including the estimation of bilirubin in the serum and of urobilinogen in the urine. The results indicated a definite liver disturbance; in 91 per cent. of the cases there was a bilirubin retention of 1 to 5 units (normal 0.4 to 0.8 unit). The urobilinogen was also increased from 1 to 35 up to 1 to 200 (normal about 1 to 20). The reactions were lowest in Group A and highest in Group C. Constipation of the spastic type, fatigue, strain, emotional factors, and sexual excesses were found to precipitate an attack. The development of an attack following the ingestion of animal protein during a period of constipation leads to a theory of intestinal toxæmia, and Diamond advances the hypothesis that migraine is due to the inability of the liver to detoxicate putrefactive substances derived from animal protein in the intestinal canal. Weight is added to this view by the marked beneficial results following the addition to the intestinal flora of *B. acidophilus*, and avoiding intestinal putrefaction. This was accomplished by withdrawing all forms of animal protein from the food, by placing the patient on a strict lacto-vegetarian diet, and by overcoming the spastic constipation so as to secure copious daily evacuations.

### 2. Injection of Veins in Arthritis Deformans.

In a series of 5,000 joint lesions of various kinds A. ZIMMER (*Med. Welt*, October 1st, 1927, p. 1310) found that a large number of patients suffered from arthritis deformans of the knee-joint with crepitation on movement, and marginal proliferation of the joint surfaces shown in the skiagram; effusion, however, was rare. When this condition was associated with varicose veins in the neighbourhood of the affected joint marked relief of such symptoms as difficulty in walking or standing up after sitting, rapid fatigue in the joints, and increased pain at night and during changeable weather, was obtained when the varicose veins were treated by injection, even though other forms of treatment had previously been without effect. One of the larger veins below the knee and as near as possible to it was chosen for injection; the veins draining away from it were compressed, the site of injection frozen with ethyl chloride, and 3 to 4 c.cm. of a 20 per cent. saline solution (varicophlin) were injected slowly into the vein from a record syringe. The pressure on the veins central to the site of injection was then released and after ten further minutes in the recumbent position the patient was allowed to return home. When pain developed in the veins during the first few days wet compresses were found useful. If necessary other veins were injected later. The possibility of an etiological connexion between the varicose veins and the joint lesion is being investigated. In another group of cases, in which a chronic arthritis of one or both knees was associated with obesity in women at about the menopause, Zimmer found that considerable improvement in the joint symptoms was produced by pluri-glandular endocrine therapy and dieting without local treatment even before any appreciable reduction in weight had occurred. Estimations of endocrine activity on the lines of Abderhalden's reactions were performed on these patients before and after treatment independently of the clinical findings, and the

curves compared with the "normal" deduced from a series of 1,400 observations. The relative value obtained for the various endocrine glands was considered of more importance than the absolute value of each. The majority of the curves were abnormal at the beginning of treatment and approached the normal as the joint symptoms subsided under endocrine treatment. Though the value of the estimations of endocrine activity is disputed by some workers Zimmer considers that they are distinctly useful, if due precautions are taken, and his observations demonstrate that endocrine disturbance may be an important etiological factor in one type of arthritis.

### 3. Sandfly Fever.

ACCORDING to S. V. VISKOVSKY and V. P. PETROV (*Meditsinskaya Mysl Uzbekistana*, September, 1927, p. 5), phlebotomus, or sandfly fever, which assumes epidemic form in Central Asia in the summer months, is due to a virus which is neurotropical and affects mainly the sympathetic nervous system. At first it circulates freely in the blood and is only subsequently fixed in the nervous tissue. The fever is transmitted by mosquitoes of the genus phlebotomus (*P. papatassii*, *perniciosus*, *caucasicus*, *li. minutus*). Systematic investigations of the cerebro-spinal fluid and of the blood pressure, as well as clinical observations, show that the actual duration of the fever is not less than two to three weeks, but the disease presents two periods—a short one characterized by an acute febrile attack, and a long afebrile period accompanied by general weakness, bradycardia, disorders of the vegetative nervous system, and increase of the intracranial pressure.

### 4. Transient Hemiplegia.

H. W. FLANNING and H. C. NAFFZIGER (*Journ. Amer. Med. Assoc.*, October 29th, 1927, p. 1484) state that transient hemiplegia is most often encountered in the aged whose vessels are sclerosed, and is rare in younger individuals whose vascular system has retained its maximum elasticity. The usual explanation, therefore, of transient hemiplegia by a vascular spasm causing a temporary localized cerebral anaemia is improbable, since spasm is unlikely to occur in thickened and hard vessels. A more probable explanation of transitory hemiplegia is cerebral anaemia due to a fall of the general blood pressure or of the venous pressure below the patient's optimum. This view is supported by the frequency of transient hemiplegia or aphasia during a meal when splanchnic dilatation with a drop of venous pressure causes a cerebral anaemia. Lowering of the blood pressure, therefore, in cases of transient hemiplegia is a dangerous measure, and should be avoided.

## Surgery.

### 5. Prognosis and Treatment of Giant-cell Sarcoma.

W. B. COLEY (*Annals of Surgery*, November, 1927, p. 641) considers that giant-cell sarcomas are usually benign and only locally malignant, but in a few cases they have the clinical features of a malignant tumour, causing death by metastases, and so should be classed as ordinary sarcoma. In the majority of cases the clinical and x-ray evidence permits a correct diagnosis to be made, but this is not always possible. Most of these tumours can be cured by enucleating and carbolic acid or zinc chloride. If the disease recurs repeated enucleating may be necessary. When a pathological fracture develops amputation is often obligatory. Giant-cell sarcoma can definitely be destroyed by radiation; the time required, however, is longer than in the case of operation, and so the period of disability is prolonged. It is possible to cure benign giant-cell sarcoma, and even advanced borderline cases, by injection of the mixed toxins of erysipelas and *B. prodigiosus* without other treatment; also it is possible to cure these cases by a combination of toxins and radiations or toxins and enucleating. The most rapid and certain method is by enucleating, followed by toxins; this requires a much shorter time, is not associated with greater risk, and so is the method of choice.

### 6. Pulmonary Abscess following Tonsillectomy.

A. OCHSNER and W. NESBIT (*Arch. of Otolaryngol.*, October, 1927, p. 330) discuss the mode of infection of the lungs when tonsillectomy is followed by pulmonary abscess. Moore had collected over 200 cases, and it was found that in nearly one-fifth the operation had been performed under local anaesthesia. The transfer of the infection must be by the

lymphatics, the cardio-vascular system, or by the tracheo-bronchial tree. Since the lymphatic drainage of the tonsillar region passes directly into the venous stream at the junction of the subclavian and internal jugular veins, infection could not travel from the tonsil by the lymph stream to the lungs. It has been shown that if infected emboli are placed in the internal jugular vein a pulmonary abscess inevitably results; attempts to produce the same result by deliberately infecting the tonsillectomy wounds in dogs have been unsuccessful. These experiments have indicated that the cardio-vascular system is not the line of infection of the lung. The aspiration theory of transference of septic material by the tracheo-bronchial tree is supported by the fact that every abscess following tonsillectomy is in open communication with a bronchus, and the cavity is lined with epithelium in part at least. The problem how the infected material passes the defences of the lung at the glottis appears to be elucidated by the fact that when the anterior pillars of the fauces or the peritonsillar region is anaesthetized by cocaine the act of deglutition is so deranged that the larynx is not raised up behind the back of the tongue, and material tends to pass through the larynx into the trachea. This has been watched in the human subject by anaesthetizing this region and using iodized oil. The authors are convinced that post-operative pulmonary abscesses are due to aspiration of septic particles.

7.

#### Gastric Linitis.

P. OURY (*Journ. de Méd. et de Chir. Prat.*, November 10th, 1927, p. 772) reports three cases of this rare form of gastric carcinoma and discusses its etiology and development. The symptoms as a rule are slow in appearing and at first do not suggest any serious gastric condition; later wasting, pain, or vomiting may arouse suspicion of malignant disease. As a rule no lump is felt and there is never any haematemesis or melæna. The diagnosis is made by radiology, when it is seen that the stomach is small and retracted, shows no peristalsis, has rigid walls, and empties itself with great rapidity, often in ten minutes. It contains little or no residual fluid, so that test meal examinations are difficult; anachlorhydria is constant. The stomach walls become almost cartilaginous, but the mucous layer is not affected. The disease may affect the whole stomach or part of it, and it sometimes attacks the intestines. Metastases seldom occur in the liver, but may appear in the rectum, especially on the anterior wall; the peritoneum may be affected by the disease spreading along the lymphatics. The metastases may be nodular or annular, constricting the bowel, and ascites is not uncommon. Since these metastatic growths do not always conform histologically to the primary growth they may be mistaken for primary multiple cancers. Diagnosis, as a rule, can only be made by radiology, and the prognosis is uniformly hopeless.

### Therapeutics.

8.

#### Gold Salts in Pulmonary Tuberculosis.

HERMANS (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, November 10th, 1927, p. 812) describes the use in tuberculosis of a combination of the salts of gold, iodine, and cadmium, the two latter adding an antibacterial action to that of the gold. In the preparation used (crystalline) the action of each of its elements is said to be increased by the others. Hübl has shown that the fixation of iodine by the non-saturated fatty acids is much accelerated by a mercury salt, and Margosches and Himmer and other investigators have stated that many metals, including cadmium, possess this same property. Since tubercle bacilli, at least at their periphery, contain non-saturated acids, it is reasonable to believe that a salt composed of gold, iodine, and cadmium would be efficacious in the treatment of tuberculosis. For some two years Hermans has used crysiodal in thirty cases of pulmonary tuberculosis, and reports five of these in detail, the drug having been administered either intravenously or intramuscularly. Some of these patients appear to have been cured, the others showing very marked improvement; only one failed to respond to the treatment. No serious ill effects followed any of the injections, and any slight symptoms that did arise occurred only during the same evening; after the sixth injection the patients declared that they felt much better. Under treatment the appetite improved, sleep was more regular and tranquil, and oppression and breathlessness diminished. The temperature progressively dropped to normal, night sweats lessened by degrees, and the weight slowly but steadily increased. Radiograms showed a diminished opacity, the shadows finally disappearing. The thorax became more mobile with increased pulmonary ventilation; the dullness gradually lessened, vocal vibrations lost their intensity, and the râles decreased. The cough improved very rapidly, and the sputum, increased at

first and after each injection, lessened as treatment progressed, became less purulent, and finally ceased. Hermans has also used crysiodal with marked benefit in cases of adenitis, and also in one of tibio-tarsal osteitis with peritonitis and discrete pulmonary lesions.

9.

#### Strophanthin in Heart Failure.

R. F. WEISZ (*Med. Welt*, October 22nd, 1927, p. 1440) states that the strophanthin prepared from different species of strophanthus differ considerably in their action: crystalline strophanthin-g (ouabain), prepared from *Strophanthus gratus*, is much more powerful in its action on the human heart than amorphous strophanthin-k, prepared from *Strophanthus kombe*; with the former the therapeutic and toxic doses are very close together and the risk of overdose is considerable. It is therefore important to distinguish between the two when estimating the effect of a given dose. The best results are obtained by intravenous injection, but special precautions are necessary; thus the author considers it advisable to use a fresh needle for injecting the solution after removing the one through which it was withdrawn from the ampoule into the syringe, so that the irritant action on the tissues of traces of the drug adhering to the outside of the needle may be avoided. Strophanthin closely resembles digitalis in its effect on the heart, but its action is much more rapid. It is also much more rapidly excreted, but, though the risk of a cumulative effect is negligible, injections should in general not be given more frequently than once in twenty-four hours, and they should not be started until two to three days after cessation of a course of digitalis. In sensitive persons vomiting from central irritation may be produced. The usual dose of strophanthin-g is 0.5 mg.; sometimes 0.3 to 0.4 mg. is sufficient, though it is considered advisable to start with an adequate dose, while 0.8 to 1.2 mg. should be the maximum. The dose may have to be increased gradually during a course of treatment, because increasing weakness of the cardiac muscle can only be postponed but not prevented. Though the blood pressure rises after the injections a moderate degree of hypotonia is considered no contraindication to their use. The main indications are myocardial weakness, especially if acute or associated with pulmonary, hepatic, or peripheral congestion, pulmonary oedema, or cardiac asthma, and disturbances of rhythm when these are due to myocardial degeneration. For these one or a small number of injections generally suffice. In more chronic cases a course of injections is required, starting daily or on alternate days and with a gradually increasing interval, until the desired effect on oedema or congestion is produced; these are followed by a course of oral or rectal doses of digitalis. In the worst cases the injections may have to be continued indefinitely. Acute circulatory failure in infective diseases, due largely to toxic damage of the peripheral vessels, is hardly affected by strophanthin.

10.

#### Treatment of Leprosy.

R. G. MEDINA (*Arch. de méd., cir. y esp.*, November 26th, 1927, p. 610) remarks that though leprosy is not so prevalent in Spain as in some other countries it occurs in most of the Spanish provinces, the foci of greatest intensity being Galicia, Levante, Andalusia, Extremadura, and the Canary Islands. Murillo reckons that the number of lepers in Spain is 800, but this figure is too low an estimate. Medina, who records fourteen illustrative cases in patients aged from 13 to 52, has obtained the best results from treatment with antileprol, a preparation consisting of a mixture of ethyl esters of all the non-saturated fatty acids contained in chaulmoogra oil. Intravenous injections were given twice a week in doses of 0.2 c.cm. at first, which were gradually increased up to 2 c.cm. Apart from slight attacks of coughing no bad effects were observed. After a hundred injections on an average the Wassermann reaction, which is constantly positive in leprosy, as well as the Hecht and Moincke reactions, became negative. A clinical cure was obtained in many cases as well as disappearance of *B. leprae* from the nasal mucus, a result which Medina had been unable to obtain with any other drug.

### 'Anaesthetics.

#### 11. The Anaesthetist in Certain Surgical Emergencies.

E. I. MCKESSON (*Canadian Med. Assoc. Journ.*, November, 1927, p. 1314) describes certain emergencies in which the anaesthetist may render exceptional assistance to the surgeon. After the relief of strangulation of the bowel the doubt whether the mesentery and gut should be returned to the abdomen or be resected may be resolved by the administration of pure oxygen to the patient for two or three minutes. If the colour of the gut definitely changes to a lighter red and

no areas retain a black or greyish-purple appearance the circulation is present and recovery of the bowel may be expected. McKesson gives examples of the value of raising for a short time the pressure under which the anaesthetic is given. In such cases as the locating of a small broncho-pneumal fistula and collapse or apnoea in a patient when pus is released from the pleural cavity by rib resection, if the anaesthetic is continued under sufficient pressure so as to obliterate the pleural cavity and force loose masses of exudate into the incision, the surgeon can clean the cavity more effectively and reduce the period of convalescence. McKesson emphasizes the importance of artificial respiration with pure oxygen under pressure in certain emergencies, and describes a method of distinguishing between the lowering of blood pressure due to the anaesthetic and that caused by surgical conditions.

#### 12. Rectal Anaesthesia.

J. MOUZON (*Presse Méd.*, November 16th, 1927, p. 1396) describes the employment of a rectal anaesthetic termed "avertine," which has the formula  $\text{CBr}_2\text{CH}_2\text{OH}$ , and was originally prepared by the fermentative reduction of bromal, but is now made by a simple synthetic process. It is a white crystalline powder melting at  $79^\circ$  to  $80^\circ\text{C}$ ., soluble in water up to 2.5 per cent. at  $20^\circ\text{C}$ . and 3.5 per cent. at  $40^\circ\text{C}$ .; at higher temperatures it is decomposed with liberation of  $\text{HBr}$ , which has a highly irritant effect on mucous membranes. After experiments on mice and rabbits, the first clinical trial was made by Butzongeliger in March, 1926, and the first publication of cases treated by Unger and Heusz to the Medical Society of Berlin in March, 1927. The chief advantages claimed for avertine over ether for rectal administration are that it can be administered with less risk of toxic concentration in the blood; that it is non-irritant to the respiratory passages, being excreted in the urine; that there are no disagreeable post-anaesthetic effects; and that, properly administered, it does not give rise to irritation of the rectal mucous membrane. Later reports have been less favourable, and doubts have been thrown on its supposed non-toxicity as regards hepatic, renal, and cardiac tissue; it is stated that only in 40 to 50 per cent. of subjects can full anaesthesia be assured by its use alone. Liquid diet only is given the night before operation; some surgeons administer morphine or pantopon one to two hours before the operation. A solution of about 1 in 40 of freshly prepared avertine in distilled water or normal saline solution at  $40^\circ\text{C}$ . is run in through a rectal tube slowly, about 0.08 to 0.15 gram being given for each kilo of body weight. The patient should go into quiet sleep in about seven minutes, and full surgical anaesthesia should be attained in a quarter to half an hour. Pallor and shallow respiration, with a slight drop in the blood pressure, supervene. Pupil and corneal reactions are somewhat variable, but may be entirely abolished without being a sign of danger. Nausea lasts two to four hours, after which time a state resembling normal sleep often ensues, with persistence of the pallor and superficial respirations. In spite of some unfavourable reports, Mouzon considers the drug worthy of a more extensive trial, and emphasizes its value in operations on the thorax and upper respiratory tract, and in cranial surgery.

#### 13. Anaesthesia in Gall-Bladder Surgery.

W. BOURNE (*Canadian Med. Assoc. Journ.*, September, 1927, p. 1031) discusses the choice of anaesthetics in gall-bladder surgery; he prefers procaine, on the ground of its being the least harmful to the liver, while lung complications are less frequent, and local infiltration under the peritoneum of the anterior wall of the abdomen after this has been opened, and anterior splanchnic injection. He thinks the method should be combined with the use of one of the gaseous anaesthetics, as much oxygen being added as is required to prevent any danger of anoxaemia. Nitrous oxide, he adds, does not produce sufficient relaxation in this type of case, and therefore requires the addition of a little ether. Ethylene, however, abolishes rigidity more readily and does not, as a rule, need augmentation by ether. The author adds that if the clotting time of the blood is known to be increased it should be shortened by giving calcium chloride in intravenous injections of 5 c.c.m. of a 10 per cent. solution in redistilled water for three successive days prior to the operation. Glucose with a large quantity of water should also be injected, since it seems to lessen the damage which some anaesthetics cause to the liver. Morphine, with atropine or scopolamine, may also be given in suitable doses, which should be so small that no ill effects are produced, such as hyperglycaemia, increased acidosis, and depression of peristaltic activity and of the respiratory centre. During anaesthesia the state of the circulation requires watching, so that with an increased pulse rate and a fall in blood pressure lasting more than five minutes shock can be prevented by intravenous injections. For the remedy of acidosis, sodium

and potassium phosphates in alkaline form should be administered in approximately the same proportions and quantities as those in which they are being excreted; they are given by the rectum in dilute solution. Care must be taken to avoid cyanosis, in view of the severe damage to the liver which follows anoxaemia.

#### 14. Regional Anaesthesia for Operations on the Spinal Column.

G. LABAT (*Brit. Journ. Anaesthetics*, October, 1927, p. 81) states that the principles involved in regional anaesthesia for orthopaedic operations upon the spinal column differ somewhat from those for other operations, since the normal landmarks have become altered by trauma or disease. He gives notes of six cases to illustrate the technique, and remarks that the anaesthetist must have a thorough anatomical knowledge in order that his procedure may be modified to suit individual distortions. Labat considers that the following practical inferences are justified. The supine position of the patient is the best because it facilitates paravertebral injection technique, affords the greatest relaxation of the back muscles, and avoids lateral distortions. In advanced tuberculous conditions the use of a 0.5 per cent. novocaine solution is advisable, even in paravertebral block, with a limit of 250 c.c.m.; it should be introduced very slowly, and with the addition of 5 drops of 1 in 1,000 adrenaline solution to each 100 c.c.m. of anaesthetic solution injected. A modified technique of paravertebral block is advocated by which the nerves are approached from a point overlying the transverse process, the same wheals being used for the field-block; the resulting ischaemia of the operative field facilitates dissection. This method of regional anaesthesia renders decompression of the cord at the level of the first and second cervical vertebrae less difficult and hazardous, and its use at lower levels of the spine is greatly to the advantage of both surgeon and patient. By its means extensive spinal fusions are possible with but little post-anaesthetic disturbance and with considerably improved prognosis, especially in the presence of active pulmonary tuberculosis. The method was not attempted in operations on children.

### Obstetrics and Gynaecology.

#### 15. Uterine Cancer and Radiotherapy.

D. DEN HOED (*Nederl. Tijdschr. v. Geneesk.*, November 19th, 1927, p. 2132) remarks that cancer of the uterus is very often infected, especially in an advanced stage. This complication may assume various forms, such as infection of the tumour, pyometra, salpingitis, parametritis, and pelvic peritonitis. Any gynaecological operation or radiotherapeutic application may aggravate this condition or rouse a dormant infection into activity. The complication may occur during treatment and assume any of the following types: fever without localization, infection of the pelvic connective tissue, pelvic peritonitis, general peritonitis, pyaemia, or septicæmia. The infection may be one of the reasons for a failure of treatment. The author concludes, therefore, that a careful clinical examination should be made of every patient with cancer of the uterus before radiotherapy; a bacteriological examination of the vaginal flora is also said to be of value. When haemolytic streptococci are present an attempt should be made to destroy them or at least to reduce their virulence, as the author succeeded in doing in some of his cases. Special care must be taken in the use of radium therapy in such patients. In every infected case local disinfectants, such as Dakin's fluid, and specific vaccine and serum treatment should be used before radiotherapy is commenced.

#### 16. Low Caesarean Section.

L. E. PHANEUF (*Boston Med. and Surg. Journ.*, November 10th, 1927, p. 825) claims that when the transverse cervical incision is used in the low Caesarean section, dividing only non-contraction tissue, the percentage of rupture of the cicatrix is reduced, convalescence is better, and post-operative complications are lessened. His technique differs from that usually adopted in that the bladder is completely separated from the cervix down to the vagina and as far as possible laterally, the incision being placed at a lower level and entirely in the cervix, so that it is retrovesical or subperitoneal at the completion of the operation. With the patient in the Trendelenburg position a six-inch median abdominal incision, starting at the symphysis, is made and the lower uterine segment wallcd off with a long strip of gauze. The uterine peritoneum is incised transversely, and the lower flap, together with the bladder, is pushed downward and protected by a Doyen retractor. A transverse incision with its concavity towards the symphysis is made as low as possible in the cervix and the child is delivered through

it. The placenta and membranes are removed through the incision unless the os is fully dilated, when they are expressed through the vagina after closure of the cervical incision and suture of the peritoneal flaps. Phaeuut has performed 35 operations by this method, with only one maternal death and a foetal mortality of 8 per cent. He adds that while there is but little bleeding, the curved incision with the concavity towards the symphysis affords plenty of room, and the procedure can be used for patients in whom a classical Caesarean section is contraindicated.

#### 17. Etiology of Stillbirth.

E. C. LYON (*Amer. Journ. of Obstet. and Gynecol.*, October, 1927, p. 548) has examined the statistics of stillbirth in 4,000 consecutive ward deliveries at the Women's Hospital, New York. He finds that 104 patients had 105 stillborn infants (25 stillbirths per 1,000 deliveries); 85 of these patients had been attending the pre-natal clinic (21 stillbirths per 1,000 deliveries); 25 patients showed evidence of toxæmia, and 4 of these had convulsions. Of 79 patients on whom the Wassermann test was performed, 9 were "four plus," but only two infants were born with evidence of syphilis. There were 61 abnormal deliveries, 22 being by forceps and 39 by breech presentations; 90 patients had normal pelvic measurements. There were 37 premature infants and 44 were macerated; 11 cases of prolapsed cord occurred, and in 10 of these it was a contributory or actual cause of stillbirth. Of 53 infants on whom an autopsy was performed, 12 showed cerebral injury. In 55 patients no foetal heart was heard on admission to hospital, and in 41 of these it was inaudible subsequently during labour. Lyon thinks that 20 of these 41 stillbirths might have been avoided if a different method of delivery had been chosen in 8 cases, and earlier operative intervention had occurred in 12.

#### 18. After-History of Pyelitis in Pregnancy.

B. C. CORBUS and W. C. DANFORTH (*Amer. Journ. of Obstet. and Gynecol.*, October, 1927, p. 544) report pyelographic studies in thirteen consecutive patients who, during pregnancy, had suffered from "pyelitis" accompanied by pyrexia. Except in two instances the observations were made from four to forty-eight months after termination of pregnancy by labour (usually) or abortion; the average time was ten months. In every instance abnormality of the urinary tract was detected; all the patients had a stricture of the ureter, ten had hydronephrosis, twelve a dilated ureter, and seven a ureteral kink. The authors' studies were occasioned by their finding that whereas cases of pyelitis in pregnancy usually yielded to treatment by posture, free ingestion of water, urinary antiseptics, and, occasionally, etherization of the ureter, the patients were frequently found to be not entirely well after delivery. They conclude that it is reasonable to infer that patients suffering from pyelitis during pregnancy have had, before conception, some morbid condition in the ureter; and they point to Hunner's reports of the frequency of ureteral stricture as a cause of upper urinary tract infections. The practical conclusion drawn is that since termination of pregnancy does not cure urinary infection patients should be treated subsequently in order to restore adequate urinary drainage, if possible.

## Pathology.

#### 19. Culture of Filterable Forms of Common Bacteria.

P. HAUDUROY (*C. R. Soc. de Biologie*, November 25th, 1927, p. 1392) has devised a method of cultivating bacteria from filtrates which by ordinary methods appear sterile. A culture of a given organism—typhoid, dysentery, colon bacilli, diphtheria bacilli, staphylococci, or streptococci—is filtered rapidly under a low pressure. The filtrate is transferred to a sterile tube and incubated. After about a week, though sometimes not for several months, a small granular sediment appears, or less often a very slight opalescence, which may later be replaced by a granular sediment. No further change occurs, even after prolonged incubation. Subculture into ordinary media is followed after a long time by reproduction of the same appearances as in the original filtrate. After numerous trials Hauduroy has succeeded in cultivating bacteria from these apparently sterile filtrates. A few cubic centimetres of a granular or opalescent filtrate are planted on the surface of a nutrient lactose agar plate. After twenty-four or forty-eight hours in the incubator the surface appears slightly dull and as though covered with a very thin deposit. The surface is scraped carefully, the material suspended in broth, and planted again on to another plate. This operation is repeated half a dozen times or so, when very tiny colonies appear just visible with a magnifying glass; these gradually increase

in size, and finally resemble the ordinary colonies of the organism from which one started. These colonies can be subcultured in the usual media. By no other method has Hauduroy been able to reproduce the ordinary forms of bacteria from filtrates.

#### 20. The Histology of Nasal Polypi.

O. BARTOLI and L. BIANCHI (*Arch. Ital. di Otol.*, October, 1927, p. 609) have made an extensive study of polypi from twenty patients. They have found that the covering epithelium varies from columnar through cuboidal to squamous epithelium. In polypi of recent formation, and especially in single polypi, the epithelium retained the typical nasal columnar formation, but as the polypi increased in age these cells became flatter until in very old polypi a single layer of flattened cells covered the polypus. The connective tissue appeared normal except that plasmocytes were found near the periphery and especially near the glands. The vessels often showed thickening of the walls with hyaline degeneration. Glands were certainly present in young polypi, but tended to degenerate in polypi of older standing. Elastic fibres were limited to the walls of the vessels. The pedicles of the polypi consisted of bundles of fibres with vessels which did not show any hyaline degeneration; there were no traces of glands in the pedicles. The authors found no excess of leucocytes in the polypi, but considered that a number of them passed through the covering epithelium to enter the mucus which covers the polypi and bathes the interior of the nose. They do not consider that there is any evidence that these polypi are neoplastic, but are convinced that they are entirely inflammatory. Recurrences are believed to be due to incomplete treatment originally, and the absence of metastases or of cachexia confirms this opinion. The authors think that the bleeding polypus of the septum, the nasopharyngeal fibroma, and choanal cystic polypus may be neoplastic, but that all other nasal polypi are inflammatory.

#### 21. Distribution of the Herpes Virus in the Tissues.

A. URBAIN and W. SCHAEFER (*C. R. Soc. de Biologie*, November 11th, 1927, p. 1279) have studied the distribution of the virus in the tissues of rabbits suffering from experimental herpes. They removed the tissues from the affected animal at or immediately before death, make a thick suspension in saline solution, and inoculated this either by the cutaneous or the cerebral route into fresh animals. The brain of each animal which died after inoculation with these tissue suspensions was tested for virulence. The authors found that the virus was always present in the brain and spinal cord, frequently in the cerebro-spinal fluid, occasionally in the saliva and the suprarenal glands, and never in the lungs, kidneys, spleen, liver, salivary glands, or striated muscles. It was detected in one specimen of urine examined immediately after passage, but not in another specimen collected twenty-four hours previously. It was also demonstrated twice out of five times in rabbits which had been inoculated with 5 c.cm. of a faecal suspension.

#### 22. The Action of Endocrine Glands on Gastric Secretion.

A. FRAGOMELE (*Il Morgagni*, October 30th, 1927, p. 1721) reviews the literature and comes to the following conclusions as the result of experiments on a dog in which he had made a small Pavlov stomach: (1) Adrenaline, thyroïdin, and pituit gland, injected subcutaneously, have a well marked inhibitory action on the gastric secretion, causing a diminution in the amount of secretion of hydrochloric acid. (2) The inhibitory action is most intense after injection of pituit gland. (3) Adrenaline, even when given in the dose of 1 mg., as was done by Loëper, does not stimulate the secretion of hydrochloric acid, as that author maintained. Frangomele adds that the investigations not only show the remarkable influence on the gastric secretion of the active principles of the suprarenals, thyroid, and hypophysis, but also help to explain the causes of gastric dyspepsia found in various affections of the endocrine glands according as they are in a condition of excessive or reduced activity.

#### 23. The Antiseptic Property of the Bile.

G. BALICE (*Il Policlinico*, Sez. Chir., November 15th, 1927, p. 501) has performed a series of experiments on dogs to ascertain the effect of cholecystectomy on the antiseptic property of the bile. He finds that the portion contained in the gall bladder plays a very important part in the antiseptic property of the total bile, and that when this is not poured into the intestine there is a notable increase in the intestinal bacterial flora. The enhanced antibacterial power of the bile in the gall bladder as compared with the hepatic bile is attributed to the greater content in the former of sodium glycocholate and taurocholate.

### 

#### 

E. MARTIN and COSTEDOAT (*Journ. de Méd. de Lyon*, November 20th, 1927, p. 589) agree that in cases of accidental drowning or suicidal death can be caused (1) by syncope, when the aspect of the person is pallid, or (2) by asphyxia due to the penetration of the lungs by water, when the aspect is blue. If restorative efforts are started early the pallid type of drowned person can usually be revived without difficulty, but in the second type the pulmonary lesions are such that in many cases treatment is without effect. The respiratory syncope is produced with a complete loss of consciousness at the moment of the fall into the water by terror, emotion, sudden chilling of the body, and the inhalation of vomited matter in the case of those who bathe too soon after meals. The sudden cessation of respiration is of benefit in that water is not drawn into the lungs, which therefore remain uninjured. The authors deal fully with the second or cyanosed type, and show that submersion is really a traumatic asphyxia, the water acting not only as an inert medium by suffocation but also by destroying the pulmonary parenchyma. Experimental evidence is given and the pathology of animals drowned is detailed. In the microscopic examination special attention is drawn to the vegetable and mineral plankton, algae, diatoms, coal dust, and siliceous shells found scattered throughout the lungs. The authors raise the important question whether simple post-mortem immersion of a corpse can cause these same changes in the lung. The most valuable sign is hypoaeration (or dry ballooning), or even emphysematous hydroaeration. The value of this sign is unfortunately destroyed by putrefactive changes. When the living membranes of the alveoli are destroyed water containing crystalline particles can enter the left auricle by the pulmonary veins. The microscopic examination, therefore, with chemical cleanliness of the fluid from the left auricle is of great value, and the authors describe the technique of this investigation as modified by themselves, using antiformin and a microscope with lateral illumination. The siliceous particles after calcination can be weighed for comparison. The practical conclusions are that syncope is a means of preservation of life, and an apparently drowned person who is pallid may often be revived by persevering with artificial respiration and rhythmic traction on the tongue over after submersion for forty minutes. In a person who is cyanosed recovery will not follow if the lungs have been invaded by water for only a few minutes. For treatment bleeding and artificial respiration in the prone or ventral decubitus should be tried, and both these methods should be used in cases of doubtful diagnosis.

#### 

J. SABRAZÈS, P. BROUSTET, and R. BEAUDIMENT (*Gaz. hebdomadaire de Sci. Méd. de Bordeaux*, November, 6th, 1927, p. 705) report a case of death almost certainly due to necrosis of the pancreas caused by the virus of mumps. A lad, aged 19, suffering from mumps, escaped from hospital during the fifth night of illness. He walked about four miles and returned in an exhausted state the following morning. He died two days later, with a syndrome of acute nephritis, pulmonary embolism, pains, and vomiting. There was no fever, and the pulse was rapid and feeble. The clinical participation of the pancreas in mumps is said by the authors to be demonstrable in one in every 250 cases. At the necropsy the pancreas was found to be greatly increased in volume; there was generalized conglutinate necrosis, both cytoplasmic and nuclear. The necrosed tissue was oedematous, but without leucocytic infiltration. Here and there were occasional signs of thickening. It was difficult to find the islets of Langerhans; in one segment there was only one islet, which was necrosed and compressed. Fibroblasts had suffered less than the parenchyma and the smooth muscular fibres. There was no haemorrhagic effusion and no thrombosis. Fat necrosis in and around the organ was evident, together with small collections of fatty acid crystals; minute hyperplastic ganglia of lymphatic material were seen round the organ. No infective organisms were found. There were no changes in the stomach, intestine, bile and pancreatic ducts, gall bladder, suprarenals, lacrymals, and thyroid gland. The infective condition of the liver, the acute nephritis, the congestion of the lungs, and the slight meningitis

goal lymphocytosis led the authors to conclude that mumps was the sole causative agent in this case, aggravated by conditions operating at the onset. The necrotic condition of the pancreas showed that it was definitely attributable to the virus of mumps. Death due to pancreatitis caused by mumps is rare. Records of such cases show that there have usually been other complications, which have made it difficult to attribute death to the condition of the pancreas.

#### 

M. TAPIA and J. TORRES (*Arch. de med., cir. y esp.*, November 12th, 1927, p. 569) had previously shown that the sedimentation rate of the red corpuscles did not possess any prognostic value in pneumonia, as there was an absence of any relation between the acceleration rate, which was constantly increased, and the pneumonic process. In the present paper, however, they maintain that the sedimentation rate has an undoubted diagnostic value, at least in the first few days of the disease, especially in conjunction with morphological examination of the blood in cases of pneumonia in which physical signs are insufficient or completely absent. They record a case of a slow sedimentation rate in which lobar pneumonia could be excluded, while the clinical and bacteriological evidence indicated the presence of a pneumo-typhoid infection.

#### 

AURICCHIO (*Il Morgagni*, November 6th, 1927, p. 1787), as the result of observations carried out on 65 children, a large number of whom were living in a community in which scarlet fever was prevalent, came to the following conclusions. (1) The Dick reaction is positive in a much larger percentage of children than that usually affected by scarlet fever. (2) Children who have recovered from scarlet fever may show a positive Dick reaction. (3) Children with a negative reaction may contract scarlet fever, and, *vice versa*, children with a positive reaction, although exposed to infection, may remain immune. (4) The Dick reaction is specially liable to be positive in children in whom the tuberculin reaction is positive. Auricchio, therefore, does not regard the Dick reaction as a specific indication of susceptibility to scarlet fever.

## 

#### 

L. CARP (*Annals of Surgery*, November, 1927, p. 702) discusses the various methods of treating carbuncles, and concludes that, while each case is a problem in itself and requires special treatment, yet certain main generalizations are possible. In large carbuncles, whether diabetic or not, the treatment of choice is said to be radical surgery. In small superficial carbuncles and some large ones, including those of the face, x-ray therapy, as an aid to pontices and carbolic acid, has given good results; if improvement does not occur in three or four days other measures, such as surgery and the circuminjection of antogenous blood, are indicated. In diabetic carbuncles the prompt establishment of free drainage is essential to prevent spread of infection; x-ray therapy without surgery is contraindicated. Carp advises the circuminjection of antogenous blood in selected cases, and thinks it is also a valuable procedure in accessible spreading infections, even though they are receiving other treatment. In his series of 153 carbuncle cases treated during the last ten years no evidence was obtained that x-ray therapy alone could bring about cure.

#### 

SINCE several autopsies after the Weber-Rammstedt operation for pyloric stenosis in infants have shown that death was due to haemorrhage from the pyloric incision or peritonitis, presumably from the migration of organisms through the exposed pyloric mucosa, C. FORANITTI (*Wien. klin. Woch.*, November 3rd, 1927, p. 1380) has revived the method devised by Loreta and first performed by Nicoli in 1900. His technique is as follows: a longitudinal incision barely 1 cm. long is made in the anterior wall of the stomach through a small incision above the umbilicus; through this curved forceps are inserted into the pylorus, and the blades are slowly and carefully separated until a small Hegar's dilator can be passed, followed by two or three larger sizes in succession. The gastrostomy incision is sutured in three layers, and if

the peritonium covering the pylorus ruptures during the manœuvre, which occurred in seven out of thirteen cases, all belonging to the second group described below, this is also carefully sutured before closure of the abdominal wound. An injection of saline solution or glucose was given on the operating table, with spoonfuls of tea some hours later, breast milk in small quantities being allowed the next day. Two deaths were recorded in the series of thirteen cases—one from pneumonia and enteritis sixteen days later, and one from pneumonia following the anastomosis. In both the necropsy showed the site of operation to be intact. The types of pyloric stenosis found at operation fell roughly into two groups: in the first the pylorus was large, pale, and hard, and the pre-pyloric part of the gastric musculature also appeared hypertrophied; in the second the pylorus seemed to be more rigid, and the stomach was not hypertrophied, but dilated and full of air, which escaped on incision. Though the author considers it possible that both conditions were temporary phases, it was noted that the first type was much more easily dilated than the second, in which increase of connective tissue appeared to play a part. He emphasizes the point that he does not advocate the dilatation method as being superior to Rammstedt's procedure, but that he considers it to be of equal value, since it eliminates some of the risks of the latter.

### 30. Osteomyelitis of the Fibula.

ACCORDING to J. PIQUET (*Rev. de Chir.*, No. 7, 1927, p. 529) acute osteomyelitis of the fibula is not so frequently described in the literature as osteomyelitis of the tibia and femur. He records eight cases affecting the fibula alone and eleven involving both the tibia and the fibula. The condition appears to be relatively rare; this may possibly be due to faulty diagnosis, the heavy origin of the disease not being recognized. The origin is usually insidious and its course subacute; the suppuration persists until the discharge of sequestra draws attention to the real nature of the condition. The disease usually starts in the lower end of the bone and extends rapidly both upwards and downwards towards the epiphysis, the rate of spread depending upon the virulence of the infection. The clinical course is characterized by the absence of general toxic symptoms and the presence of chronic suppuration of which the origin is not recognized. Rarely the ankle-joint may become involved and infection of the knee-joint is an uncommon event. Treatment by removal of the whole diaphysis has been tried successfully, but such drastic measures do not appear to be necessary. The method of choice consists in simple incision of the periosteal abscess without opening the bone, followed later by removal of the sequestra that form. Where both bones are involved the treatment is that of osteomyelitis of the tibia and opening of the abscess between the two bones of the leg.

### 31. Multiple Ulcers of the Stomach and Duodenum.

E. HOLM (*Ugeskrift for Læger*, November 3rd, 1927, p. 999) draws attention to the disparity in the figures of surgeons and pathologists with regard to the frequency with which ulceration of the stomach and duodenum is multiple. The cause of this disparity is to be explained by the fact that the surgeon is apt to overlook many an ulcer, whereas the pathologist has a much better opportunity in the post-mortem room to investigate the frequency with which multiple ulcers occur. Thus, while statistics from the Mayo Clinic published by Starr Judd and Proctor in 1925 showed that multiple ulceration was found only in 6 per cent. of 1,475 patients, this ratio is approximately 20 per cent. as found by the pathologists cited by the author; and this ratio of 20 per cent. concerns every class of ulcer of the stomach and duodenum coming to the post-mortem room. The incidence of multiple ulceration is still higher when only those cases are considered which terminate fatally as the result of perforation. After quoting various statistics bearing out this contention, the author records the observations made on 26 cases of perforation coming to necropsy at the Bispebjerg Hospital in Denmark between 1914 and the present time. In 15 of these cases the stomach was affected alone, and in 9 the duodenum alone. In the remaining 2 cases a perforated duodenal ulcer was associated with ulceration of the stomach. In 8 of the 15 cases of ulcer of the stomach the ulcers were multiple, and this was the case with 2 of the patients suffering from ulceration of the duodenum. Thus, in 12 of the 26 cases, or approximately half of the total, the ulcers were multiple. The author suggests that findings such as these should be taken to heart by the surgeon who, as soon as he has found a perforated ulcer, usually on the anterior surface of the stomach or duodenum, has closed it in some way or other, and neglects to search for signs of a second perforation elsewhere in these organs.

## Therapeutics.

### 32. Intrabronchial Medication in Asthma and Bronchitis.

E. J. KUH (*Med. Journ. and Record*, November, 1927, p. 595) describes a method of treatment for asthma, bronchitis, and similar conditions which has been used by him for over thirty years with much success. The curved tip of an atomizer is introduced over and behind the relaxed tongue—no depressor is necessary—and the patient is instructed to exhale, pause, and then inhale deeply through half parted lips. All the vapour should disappear from the mouth. The author admits that many patients cannot relax themselves sufficiently for satisfactory treatment. The solution used consists of menthol 1 to 2 per cent., creosote 1 per cent., oil of pine needles 2 per cent. in alcohol or some other mineral oil of similar density. Heavier oils clog the atomizer. Formerly this treatment was used for children, but has apparently been discarded, although both in them and in adults pertussis cleared up within ten days. The results in some cases of bronchitis and bronchial asthma were particularly good—the spray assisting the dislodgement of hitherto removable phlegm, so that within a week the patients regained restful sleep. The best results were obtained in patients with asthma, many of whom had had tonsillectomy, skin tests, or sinus operations without benefit. The author suggests that the bronchial mucous membrane is desensitized by the vapour. Cases of hay fever also responded well when the spray was directed into the post-nasal space. Acute bronchitis is said to be sometimes aborted and always relieved, but the results in bronchiectasis were only rarely satisfactory.

### 33. Treatment of Arthritis with Salts of Ortho-Iodoxybenzoic Acid.

J. E. COTTRELL (*Amer. Journ. Med. Sci.*, November, 1927, p. 623) describes ortho-iodoxybenzoic acid as a white powder (when pure) which turns reddish brown on exposure to light, definitely acid, and soluble with difficulty in water. The sodium and ammonium salts are readily soluble in water, and the iodine content of the latter is between 40 and 45 per cent. Loevenhart and Grovø have described improved methods for preparing this acid, and state that it is a physiological, oxidizing agent; when administered intravenously it is not haemolytic; it depresses the vasomotor centre, causing a fall in blood pressure, and also depresses the respiratory centre, causing apnoea in repose with spontaneous resumption of respiration. Arkia has found that the sodium salt possesses marked bactericidal action, and Hockett noted that in dogs intravenous injection of this salt stimulated the production of antibodies. Its properties are due to the oxygen in its molecule. The use of this acid in the treatment of arthritis, especially of the infectious type, is based on its germicidal power for staphylococci and streptococci, and on its power of stimulating bodily defence mechanisms. Cottrell has used it in twenty-one cases, six of which he reports, and in only one was there no response to the treatment. Improvement was shown by diminution in pain and swelling, a subjective sense of greater motility, an actual objective improvement in joint function, and an increased sense of general well-being. Intravenous injection of the ammonium salt is the best method of administration. The standard dosage is 1 gram dissolved in 1 c.c.m. of sterile distilled water given approximately twice weekly. This is introduced slowly by the gravity method, allowing ten to twenty minutes for the injection. Burning and smarting of the eyes, tongue, mouth, and nostrils, which subside in a few minutes, are felt during the injection, and after it slight malaise and perhaps nausea are experienced. More severe reactions take the form of a chill, vomiting, and purging. If intravenous injection is impracticable, or as a supplement to it, the drug may be given by the mouth or rectum. If given by the mouth the calcium salt is preferable as it causes less gastric irritation. A larger dose of 1.5 grams is given in half-grain capsules and repeated twice weekly. For rectal administration 1 or 1.5 grams of the ammonium salt are introduced in a 2 per cent. solution after a cleansing enema. Treatment is best arranged in courses of six or eight doses at semi-weekly intervals with a rest of three to six weeks between courses. Concomitant physiotherapy should be persistently used in chronic cases and deformities treated by orthopaedic measures.

34. OWING to the unsatisfactory results obtained in chronic arthritis by Loevenhart's method of sodium ortho-iodoxybenzoate administration, N. C. TRAUB (*Journ. Amer. Med. Assoc.*, October 1st, 1927, p. 1124) tried a 1 per cent. solution of the ammonium salt, 100 c.c.m. being slowly injected intravenously by the gravity method within one hour after preparation. Eight injections were given, but,

owing to the discomfort caused, oral and rectal administration was tried. When given by the mouth 0.5 gram capsules of the salt, coated with phenyl salicylate, were used, one capsule being given the first day and two on each of the succeeding thirteen days; in rectal administration 1 gram of the salt dissolved in water was given thrice weekly after preliminary cleansing enemas. Smarting of the tongue, nose, conjunctivae, and forehead, an epigastric burning sensation, and nausea followed the intravenous injections, while oral administrations caused only slight epigastric discomfort and nausea. The rectal method proved as bearable as the oral, and is said to be the method of choice when intravenous injection is impossible. Other forms of therapy, such as diathermy, peptone injections, and orthopaedic manipulations, were used concurrently in all the cases. A tabulated summary of thirty-one chronic arthritic patients treated with salts of ortho-iodoxy-benzoic acid is given, and this shows that 16 per cent. were markedly improved, 16 per cent. moderately, and 32 per cent. slightly so; 20 per cent. were no better, while in 7 per cent. the benefit was due to other therapeutic measures. While these results are not so favourable as those obtained by other investigators, Traub considers them encouraging. He adds that further study is necessary to determine the most efficacious form of the drug, the best method of administration, the size and frequency of dosage, and the mode of action.

### 35. Control of Hiccup by CO<sub>2</sub> Inhalations.

R. F. SHELDON (*Journ. Amer. Med. Assoc.*, October 1st, 1927, p. 1118) believes that hiccup as a rule is merely a symptom of some underlying condition, though it may be a disease itself. It is often part of a vicious circle which, without control, may directly lead to death. The spasmodic contraction of the diaphragm is due to an abnormal stimulation of the respiratory centre. It is known that carbon dioxide in the strength of 5 to 5.6 per cent., with either oxygen or air, increases the activity of this centre, and overcomes the lesser stimulation of hiccup, restoring normal respiration. Sheldon records eleven cases of hiccup effectively treated in this way, and believes that the results justify the statement that carbon dioxide, in proper strength, will control hiccup during its administration and for a varying period thereafter; in some cases there will be no recurrence. Since it increases the blood pressure and entails muscular effort it is exhausting, and should, therefore, not be employed for prolonged periods in the extremely debilitated or in those to whom the marked respiratory effort would be more detrimental than the continuing hiccup. There is said to be no more danger of haemorrhage in post-operative cases or of the dissemination of infection following the use of the gas than from the sudden convulsive hiccup. In most cases the carbon dioxide administration has produced no discomfort, and has stopped the hiccup at the second to the eighth breath.

## Disease in Childhood.

### 36. Asthma in Children.

T. D. CUNNINGHAM (*Radiology*, October, 1927, p. 280) states that in spite of the generally accepted belief that in small children the accessory nasal sinuses are non-existent or rudimentary, several competent observers have proved the existence of sinusitis in children. The study of clinical histories shows that the majority of cases of bronchial infection in adults started with nasal trouble and cough in childhood, and surgical intervention is far more likely to cure, or at least to produce greater relief, in childhood than in the adult. Persistent nocturnal cough and asthmatic attacks in children always suggest sinus infection. In asthma, protein sensitization has been a great help, but a large number of asthmatics are not relieved by changing foods or by desensitization, and the bronchial asthmatic case is not benefited at all. Cunningham thinks that the value of desensitization has been exaggerated. He adds that most writers on asthma and sensitization in childhood have disregarded sinusitis. The cause of improvement by change of climate is unknown. Most patients require to live at a higher altitude; if they remove to a lower altitude it must have a drier and warmer atmosphere. When convalescent, some may return to their original climate, but the majority must remain in a relatively high, dry atmosphere. Cases of bronchial asthma or chronic bronchitis in children usually showed sinus infection when examined radiographically, and also pulmonary hilum infection, with diffuse matting and lymphadenitis, less discrete than that of tuberculosis, but local treatment to ensure drainage is essential, and general hygienic measures are very important. Ultraviolet rays supply the place of much-needed sunshine. A diet rich in vitamins is beneficial, and autogenous vaccines

are sometimes useful. The only drug which assists recovery is iodine, given in small doses for a long period. Asthmatic bronchitis cannot be cured during an acute attack of asthma; the greatest relief follows treatment between attacks. When this fails, a change to a high, warm, dry climate benefits a child much more than an adult.

### 37. Nasopharyngeal Infections as a Cause of Various Infantile Diseases.

In earlier investigations H. ERNBERG (*Acta Paediatrica*, November 11th, 1927, p. 87) observed that hospital epidemics among infants were more severe in winter than in summer, that this increased sickness in winter was chiefly due to an increased number of dyspepsias, nutritive disturbances, and other allied conditions, and that these conditions were mainly caused by pharyngeal infections. Investigations have since been continued in Stockholm, and a summary is given of all cases of acute dyspepsia, cholera infantum, and septicæmia admitted to hospital during the period 1922-24. This shows that in far the greatest number of these cases pharyngeal infection, perhaps with aural and sinus complications, was one of the primary causes in the pathogenesis. Ernberg emphasizes the importance of obtaining a full history and of making a careful examination in each case; information as to antecedent colds or similar conditions in the home immediately before or when the child was taken ill should be elicited. As good and rapid a view of the pharynx, and particularly of the posterior fauces and retropharynx, as is practicable should be obtained, the sides of the neck should be examined for possible lymphadenitis, and attention paid to any aural symptoms that might indicate a previous or present nasopharyngeal infection. The author suggests that pharyngeal infection with its complications is far the most important cause of hospital epidemics among infants as well as of similar conditions in homes, such as dyspepsias, other acute nutritive disturbances, and septicæmias, and emphasizes the importance of advising mothers as to hygienic and alimentary measures.

## Obstetrics and Gynaecology.

### 38. Sacral Hernia of the Uterus.

E. FISCHER (*Zentralbl. f. Gynäk.*, November 19th, 1927, p. 2386) records the case of a woman who, at the age of 36, was found to have carcinoma of the rectum and to be five months pregnant. The pregnancy was stopped, and after left iliac colostomy the rectum was excised by the sacral route, with removal of the coccyx and the second to fifth sacral vertebrae. There was no recurrence; the patient declined further operation for closure of the artificial iliac anus, and controlled by a belt and pad a hernia which developed at the site of the sacral incision. A year later abortion was induced for a four months' pregnancy. Five years after this she again became pregnant; no subjective symptoms accompanied the first three months' amenorrhoea, but from the beginning of the fourth month she was unable to replace the sacral hernia, which progressively increased in size. On these accounts, and because also of irregular vaginal bleeding and a protrusion of the colostomy opening, admission was sought to hospital. A living child was found in the six months' pregnant uterus, which was acutely retroflected and incarcerated within the hernial sac; the cervix was tightly pressed against the back of the pubic symphysis. The pregnancy was terminated and the empty uterus was still irreplaceable; destruction of ovarian function by x rays, to avoid the danger of subsequent pregnancy, was advised, but was refused.

### 39. Parametritis and Renal Disease.

H. WARNER (*Deut. Zeit. f. Chir.*, November, 1927, p. 350) illustrates the close association between renal disease and affections of the connective tissue in the female pelvis by the following figures. Dannreuther found well marked lesions of the urinary tract in 15 per cent. of his gynaecological cases, and Schmiedeu noted the occurrence of surgical disease of the kidneys in 62.9 per cent. in women as compared with 37.1 per cent. in men. Similarly, in a study of the records of the University Surgical Clinic of the Charité Hospital at Berlin during the last five years Warner found that 55.8 per cent. of the renal cases occurred in women, as compared with 44.2 per cent. in men. He records eight illustrative cases in women aged from 25 to 51, in whom renal disease in the form of pyonephrosis, hydronephrosis, calculus, or wandering kidney was associated with parametritis. In advanced cases treatment consists only in unilateral nephrectomy, which was performed in seven of Warner's cases, and with one exception was successful.

## 40. Mode of Spread of Ectopic Endometrium.

W. MESTITZ (*Arch. f. Gynäk.*, September 1st, 1927, p. 667) strongly supports the theory recently put forward by Halban with regard to the mode of spread of extrauterine endometrioma. With Halban he regards this tissue, which resembles the glands of the corporal endometrium, as aberrant uterine mucosa which has been taken up into the lymphatic spaces lying between the musculo fibres in the myometrium, and conveyed along lymphatic vessels to the parametrium, ovary, uterine ligaments, recto-vaginal septum, parietal or visceral peritoneum, umbilicus, or occasionally to the scar of an abdominal wound, the vaginal wall, or perineum. It is a merit of the theory of lymphatic propagation that it satisfactorily explains the recurrence of endometriomata in extra-peritoneal situations, as, for example, in the perineum, or extraperitoneally at the navel. This is not explained by either of the rival theories—namely, (1) Sampson's implantation theory, according to which endometriomata arise from menstrually detached fragments of uterine mucosa which are implanted after reaching the peritoneal cavity by retrograde passage through the Fallopian tubes, and (2) the older view that endometrioma is derived from the serous endothelium of the peritoneum or surface layer of the ovary. Among the evidence adduced for Halban's theory is the frequent detection of endometrial glands deep within the myometrium and the nearness of such glands to the lymph spaces, which they sometimes invaginate; another suggestive fact is the occurrence in the regional lymph glands of the uterus of microscopical inclusions of epithelium which resembles the endometrium in form and arrangement. Such inclusions have long been known, but have not hitherto been regarded as derived from endometrium; they have been found in cases of malignant and benign uterine tumours, adnexal inflammation, intestinal neoplasm, and ulcerative colitis, but never apparently in males. An endometrial fragment, it is admitted, has not yet been detected within a lymph vessel. Sampson's implantation theory has recently found much support, but its adherents admit that it fails to explain all the localizations of the tumour in question, and Sampson himself has recently suggested that in certain cases this is spread not by implantation but by conveyance along small veins.

## 41. Prevention of Post-operative Peritonitis and Abdominal Adhesions.

H. L. JOHNSON (*Surg., Gynecol. and Obstet.*, November, 1927, p. 612) recommends the introduction of amniotic fluid into the abdomen in cases of Caesarean section to prevent adhesions. As the result of experimental and clinical observations he finds that this fluid prevents peritonitis by setting up a fibrinous wall of defence and inducing a moderate local leucocytosis. Adhesions did not form because the proteolytic ferments in the fluid, due to the local leucocytosis, stimulated rapid resolution of the plastic exudate. The amniotic fluid is sterilized by passage through a Berkefeld filter. Johnson has tried the method with success in fifty-three cases of abdominal Caesarean section, in eighteen of which a second operation was performed, enabling the author to examine the remote results of this procedure. In one patient the uterus had ruptured twenty-four hours before the operation, and in another an infection of the abdominal cavity seemed certain, but in neither case did peritonitis develop.

## Pathology.

## 42. The Exhaustion of Media in Bacterial Cultivation.

M. S. PALEVICI (*Giornale di Batteriologia e Immunologia*, November, 1927, p. 721) brings evidence to show that the main factor in the cessation of growth on artificial media is not the development of toxic substances, but the rapid exhaustion of certain accessory food substances. In his first series of experiments he cultivated a strain of staphylococcus on a number of agar slopes; after three days at 37° C. he washed off the growth with sterile distilled water, and reinoculated the tubes with the same strain. No growth occurred. After twenty-four hours he again washed the slopes, and then divided them into two lots: to one lot he added two to three drops of fresh sterile lemon juice, allowing the juice to flow over the surface of the agar; the other lot were boiled, and the same quantity of lemon juice was added to each before the agar set again. The tubes of both series were then reinoculated with the same strain of staphylococcus and incubated; growth occurred regularly in every tube to which lemon juice had been added, but did not occur in control tubes to which no juice had been added. Control tubes to which lemon juice had been added, but which were not inoculated, remained sterile. The experiment was repeated with various modifications. It was found that the

lemon juice exerted the same growth-promoting action even after it had been autoclaved at 134° C. for half an hour. Similar results were obtained when grape, apple, or pear juice was substituted for lemon juice, and when *B. coli* and paratyphoid bacilli were substituted for staphylococci. In a third series of experiments he showed that lemon juice had a stimulating effect on the growth of tubercle bacilli on egg medium. The author concludes that fruit juices owe their growth-promoting properties to the presence in them of accessory food substances or of thermostable vitamins.

## 43. Typhoid and Dysentery Antibodies in Mental Patients.

ACCORDING to F. A. PICKWORTH (*Journ. Path. and Bact.*, October, 1927, p. 627) diseases of the typhoid and dysentery groups have been in the past specially common in mental hospitals. Mott and Durham, in their study of asylum dysentery in 1900, showed the lesions to be of the bacillary type, although a specific dysentery organism was not generally found. During the period 1925-27 the agglutination results of 2,533 serums of patients in the Birmingham Mental Hospital to nine standard organisms were examined (*B. typhosus*, *B. paratyphosus* A, *B. paratyphosus* B, *B. paratyphosus* C, Gärtner's bacillus, *B. aertrycke* (Minton), *B. aertrycke* (Newport), *B. dysenteriae* Shiga, and the Y bacillus), and no fewer than 619, or 24.7 per cent., gave positive results. It is noteworthy, however, that positive results were found in 107 out of 464 new admissions, or 23 per cent. These figures, therefore, to a considerable extent exonerate the institutions (apart from epidemics) from at least part of the blame of spreading intestinal diseases, and support the view that intestinal infections may have an important bearing on the etiology of mental disorders. Over two thousand specimens of faeces were examined, but only a few pathogenic organisms were found.

## 44. Resistance of Acid-fast Bacilli to Oil Emulsion.

T. TODA (*Journ. Orient. Med.*, November, 1927, p. 91) believes that acid-fast bacilli, such as those of tuberculosis and leprosy, are enabled to resist antibacterial agents by the presence of much lipid in their bodies, and that, if this acid-fastness could be removed by utilizing oil, therapeutic substances might act on the bacilli and tuberculosis and leprosy be easily cured. Toda conducted a series of experiments with tubercle and other acid-fast bacilli. He used a variety of oils, and emulsions of these oils were prepared with Arabian gum as sterile as possible, and mixed in various dilutions with 10 c.cm. of 3 per cent. glycerin bouillon. The bacilli were transplanted into these media and incubated at 37° C. for several weeks. Toda found that oil emulsion has a growth-inhibiting action, the most effective oils in this respect being hydriocarpus, rosvet, sabina, lavender, and thyme. The gum contained in the emulsions did not hinder the growth of bacilli. Human and bovine tubercle bacilli were found to be less resistant to the oil than avian bacilli and other saprophytic acid-fast bacilli, and the lipid substances were removed from them.

## 45. The Serum Calcium in Urticaria.

S. S. GREENBAUM (*Arch. Derm. and Syph.*, November, 1927, p. 553) estimated the blood serum calcium content in sixty-three cases of urticaria, and in all except one found it normal or increased. The coagulability of the blood was tested in about half these cases, and a tendency towards shortening of the clotting time was detected. Several cases grouped as allergic showed increased or normal coagulability, with no decrease in the serum calcium content. The author concludes, therefore, that the exhibition of calcium salts in the majority of urticaria cases has no scientific basis. The undiminished coagulability of the blood in urticaria contrasts with the findings in experimental allergic shock in animals. He suggests that in subacute cases of urticaria ephedrine may be of value as an adjunct to adrenaline, and may also be used when the patient's tolerance to the latter is low.

46. *B. aertrycke* Infection of Animals Killed in Slaughterhouses.

I. GHEORGHIU and G. COSTIN (*C. R. Soc. de Biologie*, October 13th, 1927, p. 1025), working at Jassy in Rumania, encountered a case of human infection with *B. aertrycke*, and decided to investigate the frequency of this organism in animals met with at the abattoir. They examined the blood and gall bladder of 385 animals, cultures being made directly after the animals had been killed. *B. aertrycke*, which was identified by the fermentation, agglutination, and complement fixation reactions, was isolated nineteen times—that is, from 4.9 per cent. of animals. The authors think that the presence in the blood of organisms which are primarily inhabitants of the intestine may be explained by the circumstance that the animals were driven twelve to eighteen miles to the abattoir, and were not killed until some hours later.

47. **Late Results of Treatment by Artificial Pneumothorax.**

H. BJELKE (*Tidsskrift f. d. Norske Lægefor.*, November 1st, 1927, p. 1278) has investigated the after-histories of the 111 patients given artificial pneumothorax treatment at the Vensmoen public sanatorium during the past ten years. In 41 cases the disease was mainly of an exudative, progressive character, 5 of the patients belonging to the second and 36 to the third stage of the disease as classified by the Turban-Gerhardt system. Cavities were demonstrable in 31 of these 41 cases, and whereas 40 were sputum-positive on admission, only 29 were so on discharge. As many as 23 of these 41 were discharged as improved. On investigation, however, 36 were found to be dead, and among the 5 survivors there was only one who could claim as long an interval as three years between the treatment and the present investigation. The results were very different in the case of the remaining 70 patients, whose disease was mainly of a productive, chronic character. There were 36 in the second and 34 in the third stage of the disease. Cavities were demonstrable in 56, and tubercle bacilli were found in the sputum in 69 of these 70 cases. On discharge, only 18 of these 70 patients were still sputum-positive, and 65 were discharged as improved. The investigation of their after-histories showed that 58 were still alive, only 12 having died. During the ten years under review the choice of patients for this treatment underwent considerable modifications. During the first five years—that is, up to 1922—most of the patients suffered from severe disease of the exudative, progressive type. During the last five years the patients selected for treatment suffered as a class rather from the productive than from the exudative type of the disease; and of the 63 patients treated during this last five-year period as many as 53 were found to be fit for work when the present investigation was made, only one patient being unfit for work, and 9 having died. The author emphasizes the importance to their surroundings of patients being discharged from the sanatorium sputum-negative, and in this connexion he notes that, though as many as 109 of the 111 patients had tubercle bacilli in the sputum before a pneumothorax was induced, 62 left the sanatorium sputum-negative. There was no case of gas embolism in this series.

#### 

48. **Watch-strap Dermatitis.**

H. GOODMAN (*Urol. and Cutan. Rev.*, October, 1927, p. 648), who records an illustrative case, suggests that this condition is commoner than his experience or the reports he has seen would indicate, since cases of dermatitis among leather writers and tanners have been frequent. His patient was a woman, aged 24, who complained that for ten days she had been annoyed by a reddened area about the left wrist where she carried her watch. Although she had worn the strap for several months she had never been troubled before, and thought that the perspiration of a recent hot spell had caused the eruption. She removed the strap to the right wrist, on which she noted a similar redness and itching forty-eight hours later. On examination it was found that the lesions were limited to the forearm. Surrounding the left wrist was an area of erythema surmounted by closely crowded small vesicles. The part of the surface upon which the watch rested was least affected. Although the strap was only half an inch wide, the left forearm was erythematous half-way up to the elbow. The more recently exposed right wrist showed an area of erythema and vesicles more nearly that of the strap.

#### 

49. **Causes of Blepharospasm.**

O. ORLANDINI (*Giorn. med. d. Osp. Civ. di Venezia*, September-October, 1927, p. 140), who records two illustrative cases in sisters aged 22 and 16, states that the causes of blepharospasm consist in a direct or reflex irritation or stimulation of the facial nerve in its peripheral portion, in its passage to its nuclei of origin, or, lastly, in its cortical motor centre. The reflex causes of blepharospasm are chiefly irritation of the trigeminal nerve, and consist in ocular or periorbital trauma or inflammation of the eyeball and its adnexa (keratitis, conjunctivitis, ulcers, iritis, blepharitis, dacryocystitis, and so on), or in pathological excitability of the sensory tracts, and in the case of the latter, blepharospasm is found to be due to disturbance of accommodation and errors of refraction. Lastly, the irritation may originate in a distant region, as in the case of children suffering from intestinal worms and in uterine disease.

Blepharospasm may be due to a direct cause, such as trauma in the region of the facial nerve, compression by tumours, caries of the petrous bone from otitis, and parotid abscess. Infectious diseases and intoxications, such as syphilis, alcoholism, and malaria, may also give rise to motor disturbances in the orbicularis. The etiological factor may be found in tuberculous meningitis and diseases of the brain with irritation of the facial nerve by compression or a meningeal exudate. In other cases the origin of the blepharospasm cannot be determined, and therefore the motor disturbance is regarded as functional or dynamic. Blepharospasm is, in fact, ranked among the motor anomalies of neuroses and psychoses, such as epilepsy, chorea, and especially hysteria, in which it is usually found on both sides.

#### 

50. **Chronic Visceral Polysteatosi.**

M. COUTO (*Ann. de Méd.*, November, 1927, p. 449) describes a clinical complex, at first sight seemingly due to arteriosclerosis, but differing from it in that it is not a sclerosis but a steatosis of the affected viscera. The condition is comparable with that found in yellow fever, which is an acute infectious polysteatosi, and in which the cells of all the organs are filled with fat droplets, their nuclei also being more or less attacked. The sole etiological factor in chronic polysteatosi is alcohol. The differential diagnosis between arterio-sclerosis and steatosis can be made by a careful examination. In both the heart is enlarged, but in the former the left side is chiefly involved, the precordial shock is strong and diffuse, the bruits are accentuated and the gallop bruit is frequently present, hypertension occurs, and the pulse is hard. In steatosis the right side is principally affected, the precordial shock is weak or absent, the cardiac sounds progressively lessen even to the extinction of one or the other, hypotension is present, and the pulse is soft. At the end of the disease the precordial shock becomes strong and diffuse and the bruits clearly perceptible, uramic symptoms develop, and death occurs from cardiac insufficiency. In steatosis, emaciation due to pancreatic insufficiency and other causes, asthenia resulting from suprarenal insufficiency, delirium, vertigo, vomiting, oliguria, albuminuria, and cylindruria are present. The liver is always enlarged and palpable, and lutenus is seen. An ophthalmic complex, the buphthalmus of Lelaidre, always occurs; this consists of a slight oedema of the eyelids, dull yellow sclerotics, and the areolæ senilis. The lesions and symptoms may be more marked in some organs only; they are sometimes isolated, and occasionally combined, forming the various clinical types—cardiac, renal, and cardio-renal. While death usually ensues, recovery may occur, as in a case noted by Couto. Opinions differ as to whether the condition is a fatty infiltration or degeneration of the cells.

#### 

51. **Oedematous Influenzal Laryngitis.**

A. RIGAUD (*Thèse de Paris*, 1927, No. 167), who records five cases in patients aged from 23 to 36, including three hitherto unpublished, states that acute oedematous laryngitis in influenza, which was first described by Wolfenden (*JOURNAL*, 1890, vol. i, p. 541), may present all degrees of severity, its intensity ranging from a slight interference with respiration to asphyxia requiring tracheotomy. The general symptoms are very variable, the sole constant one being a high temperature. The diagnosis can only be made by exclusion of all other causes of laryngeal dyspnoea. Thus, in children, cases of acute dyspnoea must be excluded, such as laryngeal diphtheria, laryngismus stridulus, foreign bodies, and causes of chronic dyspnoea, such as congenital laryngeal stridor, papilloma of the larynx, cicatricial laryngeal stenosis, and hereditary syphilis of the larynx. In the adult it is necessary to eliminate acute causes such as Bright's disease, angioneurotic oedema, iodine inflammation, acute infectious diseases, cancer, gout, laryngeal paralysis, and erico-arytenoid arthritis, and chronic causes such as tumours and sclerema. There is no specific treatment, but palliative measures and intubation or tracheotomy must be employed as required.

#### 

52. **Sex Differences in Pulmonary Tuberculosis Deaths.**

P. PUTNAM (*Amer. Journ. of Hyg.*, November, 1927, p. 663) has made a statistical analysis of the mortality and population data of the U.S. Registration States of 1900 and the District of Columbia during the period 1870-1920, in order to determine the influence of sex on the death rate from pulmonary tuberculosis. For the first five years of life he finds a slight excess of male over female deaths. This is reversed at the

ages of 5 to 24 by a female excess, with the maximum between 10 and 14, when the proportion of female to male deaths is 100 to 39. The ratios swing back between the ages of 25 and 44, after which there is a marked excess in male deaths, reaching its maximum at the ages 45 to 54. The male prevalence persists till the age group 75 and over is reached, when the male and female death rates are approximately equal. The two most striking observations are the constant excess of female deaths during the 5 to 24 age groups throughout the fifty years examined, and the excess of male deaths during the 35 to 75 age groups. This excess has become far more evident during the last thirty years; for example, in 1880 the ratio of male to female deaths at ages 45 to 54 was 110 to 100, but in 1920 it had risen to 230 to 100. From a critical analysis of his data the author comes to the conclusion that sex differences at ages under 25 are due primarily to biological causes, related chiefly to physiological changes occurring during puberty and adolescence. The differences at ages 35 to 75, on the other hand, he ascribes to environmental causes, related to the greater wear and tear on the physiological resistance of men.

53.

#### Syphilis and Marriage.

F. PINKUS (*Méd. Klinik*, November 18th, 1927, p. 1767) reports the case of a man infecting his young wife six years after he had contracted syphilis; he had no symptoms, nor had he received treatment, but nineteen years later he died from aortic and cardiac syphilis. Syphilis may remain dormant for years and then suddenly become active. Pinkus also reports the case of a man who was apparently cured by treatment but yet infected his wife, and subsequently, when actually cured, was reinfected by her. The author believes that these patients should not marry within five or six years after the date of infection, and in the meanwhile should have frequent Wassermann tests of both the blood and the cerebro-spinal fluid. Organic disease of the central nervous system is said to occur most frequently within six years of the date of infection. He adds that an untreated syphilitic woman may give birth to a congenitally syphilitic child twenty years after she was infected, and that it is probable that there is a larger percentage of untreated cases among women. When a woman has received adequate treatment she should not marry for seven years, and be kept under observation during that period. E. FINGER (*ibid.*, p. 1769) states that even after ten or twenty years a syphilitic patient may still be infectious, but he thinks that these patients may marry when four or five years have elapsed since infection, provided that they have had prolonged and energetic treatment every six months and that they have been entirely free from symptoms for two or three years. In women the period of observation should be extended to six or seven years. J. JADASSOHN (*ibid.*, p. 1770) thinks that a syphilitic man, in selected cases, may marry four years after infection, provided that he has been treated on the most modern lines, and that repeated examinations of the blood and cerebro-spinal fluid have been invariably negative for at least two years.

## Surgery.

54.

#### Wound Infection and Catgut.

F. L. MELENEX, F. B. HUMPHREYS, and L. CARP (*Surg., Gynecol. and Obstet.*, December, 1927, p. 775) report an unusual fatal operative wound infection yielding a pathogenic anaerobe of the gas gangrene group not hitherto described, and referable to catgut. A clostridium was obtained which differed culturally from the other known species associated with human gas gangrene—such as *C. welchii*, *C. oedematis maligni*, *C. novyi*, and *C. histolyticum*; it produced a true exotoxin not neutralizable by the antitoxins for any of the others, and the specific antitoxin was ineffective against any of their toxins. The occurrence within four days of four other fatal wound infections of the gas gangrene type in the same hospital led to an investigation of the theatre technique, and it was found that the chronic catgut in use at the time yielded on culture *C. novyi*, two strains of this newly described species, two different strains of haemolytic *C. welchii*, and two other non-pathogenic spore-forming organisms. Clinically the organism recovered produced a painful, brawny, red, oedematous swelling around the wound, with fever, leucocytosis, feeble rapid pulse, nausea, and profuse perspiration, and terminating in somnolence, prostration, and circulatory failure; it was highly pathogenic for the eight different species of laboratory animals tested. The authors point out that these findings call for the establishment by manufacturers of adequate aerobic and anaerobic methods for the absolute demonstration of sterility of all catgut put upon the market.

55.

#### Primary Carcinoma of the Bronchi.

T. MCGRAE, E. H. FUNK, and C. JACKSON (*Journ. Amer. Med. Assoc.*, October 1st, 1927, p. 1140) state that statistics show that malignant disease of the lung is increasing in frequency, though neoplasms originating in the lung parenchyma comprise only 10 to 15 per cent. of all lung tumours. The great majority start in the bronchi and subsequently invade the lung tissue. From an analysis of 90 cases reported by Weller, 128 cases collected from the literature, and 14 observed by themselves, the authors deduce certain clinical features of primary bronchial carcinoma. Approximately 91 per cent. of the patients were past the age of 35, and males predominated in the proportion of 4 to 1. In 40 per cent. the right side was involved, in 47 per cent. the left, in 9 per cent. both sides, while in 4 per cent. the site was undeterminable. The onset, usually insidious, may be sudden, with pulmonary haemorrhage, pain in the chest, or symptoms of acute bronchitis. Cough, presenting no special characteristic, was present in all the cases. The expectoration varied from a scanty mucoid fluid to a profuse, mucopurulent, fetid discharge. In some instances the sputum revealed fragments of tumour tissue, but the "currant jelly" sputum, said to be characteristic, was rarely encountered. Tubercle bacilli were never found unless tuberculosis was also present, and the absence of these has some diagnostic importance. Haemoptysis, a frequent and important symptom, usually appeared early in the disease, and varied from mere streaking of the sputum to default haemorrhage. Dyspnoea was common, and pain in the chest occurred frequently. In general, the early physical signs were those of bronchial obstruction; they became more intense as the obstruction increased. Weakness, loss of weight, and pyrexia were usually present, though the fever was largely dependent on the presence of an associated infection. The blood showed either a normal count or varying degrees of anaemia and leucocytosis. Metastases were found after death in about 66 per cent. of the cases, and the authors believe that bronchial carcinoma metastasizes occurs late in the course of the disease. The malady must be distinguished from tuberculosis, foreign body in a bronchus, abscess, pressure on a bronchus from without, changes peripheral to the new growth, and cancer of the trachea. The surest and most essential method of diagnosis is bronchoscopy. These bronchial tumours appear to have a relatively low malignancy, and early diagnosis, followed by intensive x-ray therapy, may at least prolong life. The authors maintain that by bronchoscopy a positive diagnosis can almost always be made promptly, and that patients with obscure pulmonary and bronchial symptoms have a right to the benefits of this procedure.

56.

#### Technique in Prostatectomy.

M. CHEVASSU (*Bull. et Mém. Soc. Nat. de Chir.*, November 26th, 1927, p. 1256) describes the methods he has adopted with considerable success in the operation of suprapubic prostatectomy; in a series of 27 cases he had uniformly successful results. He performs the operation in one stage whenever possible, and only uses the two-stage method in exceptional circumstances, for he considers it unnecessary to inflict two operations on any patient who is not in very poor condition. Moreover, removal of the prostate is much more difficult when the operation is performed in two stages. Chevassu states that the operation can be extremely rapidly performed, often in less than a minute. He uses ethyl chloride anaesthesia on a mask, which lasts for three minutes and is devoid of any risk. He never packs the cavity left after removal of the gland. Haemorrhage is controlled by flushing with hot water, but it is important that the cavity itself should be actually flushed; for this purpose he uses a special type of irrigator. The absence of packing is said to give the patient a better and more comfortable convalescence.

57.

#### Peritonsillar Abscess.

KOWLER (*Rev. de Laryngol., d'Otol. et de Rhinol.*, November 15th, 1927, p. 662) considers that the collection of pus known as a peritonsillar abscess is wrongly named. He says that the abscess that occurs is always in the palato above the supratonsillar fossa. It forms in the space between the palatal ends of the palato-glossus and the palato-pharyngeus muscles which is normally filled with loose areolar tissue. The reason why the abscess is sometimes not discovered is that the knife is caused to enter the anterior pillar and explore the region behind. Although the anterior pillar is often red and bulging the pus is rarely found behind it, and it is significant that a collection of pus between the tonsil and the posterior pillar is of the rarest occurrence. In support of this the author cites two cases of Menzel where an abscess occurred more than a year after the complete removal of the tonsil, and on incision revealed no trace of tonsillar tissue. In another case an abscess of the palato occurred in two successive years, and after the second attack

the tonsils were completely removed. In the following year another abscess appeared and was incised; in the fourth year this was repeated. The author states that in cases of abscess in association with the tonsil the pus is always in the thickness of the palate, no matter where the swelling appears most prominent, and he advises that it should always be sought there.

#### 58. Rectal Fistula in Tuberculosis.

W. A. FANSLER and C. K. PITTER (*Minnesota Med.*, November, 1927, p. 699) believe that tuberculous patients have a tendency to rectal fistulae, which occur in 3 per cent. of all cases of this infection. Clinical examination alone will often be sufficient to establish the tuberculous nature of a fistula, but a number of apparently simple lesions are on closer study found to be tuberculous. The finding of tubercle bacilli in smears of pus from an unruptured abscess, or as the result of animal inoculation, and in sections of the diseased tissue, will confirm a diagnosis made on clinical grounds, but repeated sections may have to be cut in order to demonstrate the character of the lesions. The authors doubt whether a fistula is ever primarily tuberculous. The form of operative treatment recommended is the cauterization alone or combined with dissection, depending on the needs of the case. The authors consider that operative intervention should be seriously considered in all cases of tuberculous fistulae.

#### 59. Treatment of Liver Abscess.

E. BRESSOT (*Bull. et Mém. Soc. Chir. de Paris*, October 21st, 1927, p. 620) records his experiences in treating amoebic abscess of the liver by evacuation without drainage in a series of five cases. Local anaesthesia was used in four cases. The liver was exposed by one of the ordinary incisions and the abscess opened under full vision. The pus was examined at once, and during this time the abscess was evacuated by using a Potain's aspirator. The cavity, when emptied by the aspirator, was freely opened and swabbed; the walls were never curetted. The liver opening was then obliterated by careful suturing. In the pus did not influence the line of treatment, but emetine was given subsequently. The post-operative course in all cases was straightforward and the temperature fell quickly to normal; sometimes the temperature was raised the day after operation, but this was of no significance. In eight to fifteen days the wound was healed, contrasting favourably with the fifty to 120 days required for cases that were drained. The rapidity of the recovery and the excellent results obtained are thought to render this method superior to any other that may be employed.

#### 60. Carcinomatous Degeneration of Rectal Adenomas.

F. C. YEOMANS (*Journ. Amer. Med. Assoc.*, September, 1927, p. 852) reports seven cases of rectal adenomata, in six of which adenocarcinoma developed. He concludes that although a solitary adenoma may exist for many years without becoming malignant, yet that it ought to be considered precancerous and be removed. The more sessile is the growth the greater is the tendency to malignant metamorphosis, and Yeomans thinks that the more frequent use of the proctosigmoidoscope would enable such tumours to be dealt with early and successfully. An accessible polypoid adenoma can usually be snared and cut off safely, but the more sessile growth requires wide excision of the base and cauterization or coagulation of the site of attachment. Solitary high pedunculated growths may sometimes be safely snared. When the tumour is sessile but removable it may already be malignant. Electric coagulation or radon implantation should be used as a safeguard against dissemination. High-lying sessile growths may have to be removed through an abdominal incision—a more dangerous procedure owing to the risk of peritoneal infection.

## Therapeutics.

#### 61. Treatment of Excessive Sweating.

W. CURTH (*Med. Welt*, November 12th, 1927, p. 1518) discusses the treatment of general and local hyperhidrosis; the general type occurs in pneumonia, typhus fever, tuberculosis of the lung, Basedow's disease, brain tumours, and cachexia. Atropine, though very useful, has the disadvantage of arresting the salivary secretion, causing dryness of the mouth, and inciting cough in a very distressing way to the patient. Curth thinks it better, therefore, to employ agaricin, 130 gram, in pill form, every evening, or fluid extract of hydrastis, 25 to 30 drops three times a day. Arsenic given

for a long time in small doses is strongly recommended; an infusion of sage leaves, or a tincture of sage leaves, 20 drops three or four times a day, is also useful. All these remedies, with the exception of sage, seem to influence the sweat glands through their nerve supply. Daily baths at a temperature of 80°F. are advised, and friction with some alcoholic solution, eau-de-Cologne, lavender or thyme or menthol solutions 1/2 per cent. Adipose persons require some dusting powder; but a powder containing salicylic acid is contraindicated in lung diseases, since it irritates the organs of breathing. The powder most employed is salicylic acid 2 per cent., iris root 10 per cent., zinc oxide and bismuth subnitrate each 20 per cent., with talc powder to 100. For sweating and malodorous feet Curth recommends horsehair or straw movable inner soles to the shoes dusted with a 30 per cent. sodium borate powder, as are the stockings or socks. The toes should be separated with cotton-wool, and the feet washed each evening with spirits of wine, eau-de-Cologne, or 2 per cent. salicylic acid in alcohol; afterwards they should be dusted with 3 per cent. salicylic acid mixed with equal parts of bismuth subnitrate and talc powder to 100. Painful fissures on the feet should be painted with 1 to 2 per cent. of silver nitrate before applying an ointment. For sweating in the axilla Curth recommends concentrated acetic acid 60 per cent., spirits of lavender and spirits of rosemary each 1 per cent., spirits of cloves 1/2 per cent., camphor 8 per cent., aromatic spirits of vinegar to 100. For clammy hands he also recommends a spirit solution, either 5 per cent. salicylic acid or the following: formic acid and chloral hydrate each 5 per cent., Peruvian balsam 1 per cent., dilute spirit to 100. For sweating of the head he recommends cold water douches and subsequent friction with spirits of ether 50 per cent., tincture of benzoin 7 1/2 per cent., and a few drops of vanilla, heliotrope, or oil of geranium; at night a salicylic powder may be used.

#### 62. Indications for Synthalin in Diabetes.

A. H. A. MARTENS, C. H. KOERS, and C. DE JONG (*Nederl. Tijdschr. v. Geneesk.*, November 5th, 1927, p. 1918), who record 11 cases of diabetes in patients, aged from 14 to 71, treated with synthalin, summarize their conclusions as follows: (1) Synthalin reduces the amount of sugar in the blood as well as in the urine. (2) The use of synthalin may be of service not only in mild and moderate cases of diabetes but also in acidosis after or in association with a course of insulin treatment. (3) It is desirable to test the hepatic function before commencing synthalin treatment. (4) Increase of urobilin or urobilinogen hardly ever occurs after administration of synthalin. It cannot, therefore, be regarded as a contraindication for synthalin treatment. (5) A sequel of synthalin treatment to which no attention has been drawn is the frequent occurrence of loss of flesh. (6) The complications of synthalin treatment are usually of short duration and are no indication for the suspension of the treatment. The administration of fractional doses usually causes the symptoms to disappear. (7) Any cholinergic has a good effect in causing disappearance of the symptoms. This supports the view that an efficiently functioning liver is the principal requisite for synthalin treatment. (8) The success of synthalin is not dependent on good gastric function, since synthalin treatment had a favourable effect in several patients with achlorhydria. (9) Treatment with synthalin requires special attention to each individual patient even more than insulin does.

#### 63. Chemotherapy in Septicæmias.

E. VAUCHER and Mlle UHRIG (*Paris méd.*, December 3rd, 1927, p. 454) assert that some chemical products have given very good results in the treatment of infections, and they describe four in particular—trypaflavine, mercurochrome, septicemine, and optochine—and the conditions in which they have proved of benefit. Trypaflavine is a brownish-red powder, soluble in water, forming a yellow solution. This should be sterilized for one hour at 70°, and, as it is sensitive to light, should be kept in dark bottles or ampoules. It possesses a marked bactericidal action, and acts as a powerful disinfectant in the blood, serum not modifying its action. Trypaflavine is said to be only slightly toxic, and is usually administered in 2 per cent. solutions. Slight reactions, including a yellow coloration of the skin, without shock, follow the injections. Normally it is excreted in the urine in thirty-six to forty-eight hours. Indications for its use are septicæmias in general, septic endocarditis, all infections, and typhoid fever; it is contraindicated in acute hæmorrhagic or chronic nephritis. Mercurochrome, the sodium salt of dibromoxy-mercury-fluorescein, contains 26 per cent. of mercury, and is soluble in water, forming a cherry-red solution. It possesses great penetrating and bactericidal powers, and causes only slight irritation of the tissues. A 1 per cent. solution is usually injected intra-

venously, the dose being 5 mg. for each kilo of body weight; it causes rather marked reactions. The drug is eliminated in the urine and faeces. Mercurochrome has been used with benefit in many infections, as septicaemia, pneumonia, and scarlet fever, and as a wet dressing in cutaneous infections. Optochine or ethylhydrocupreine, a quinine derivative, is liable to cause aural and ophthalmic troubles, and its use needs careful supervision, but it has given good results in pneumococcal infections owing to its selective action on the pneumococcus. Sopticeimine contains 33 per cent. of iodine and 45 per cent. of formine; it is extremely diffusible, non-toxic, and strongly germicidal. The drug causes no reactions, and is eliminated by the kidneys. It is said to be indicated in all general infections, particularly the puerperal, in septicaemias, and in pyaemias. The authors discuss the combining of these drugs with vaccines and serums in the septicaemias due to streptococci, staphylococci, colon bacilli, pneumococci, and gonococci.

#### 64. Treatment of Typhoid and Paratyphoid Fever with a Staphylococcal Vaccine.

V. BIE (*Ugeskrift for Læger*, November 24th, 1927, p. 1072) has, since 1921, been treating typhoid and paratyphoid fever with vaccines. During the first two years a typhoid vaccine was given. Later a staphylococcal vaccine was used, as its action was equally effective and the treatment could be started at once on the strength of a clinical diagnosis without the subsequent serological diagnosis being rendered difficult by artificial changes in the Vidal reaction. On five successive days intramuscular injections were given, the doses being 100, 200, 400, 700, and 1,000 million organisms. In the few cases in which this series of injections proved ineffective it was repeated after an interval of a few days. There was no more than a slight rise of temperature, and a rigor was observed in only one case. No patient collapsed under this treatment. The result was usually a fall of temperature by lysis during or directly after the injections. All the 51 cases of paratyphoid fever thus treated were severe. In 39 the result was good, the temperature falling during or directly after the injections; in 4 cases the fall of the temperature was slow, or the effect of the injections was doubtful, and in 8 cases the treatment seemed to have no effect. None of those 51 patients died. Of the 54 patients suffering from moderately severe, or severe, typhoid fever 35 responded satisfactorily to the treatment; its action was doubtful in 3 cases, and ineffective in 9; 7 of the patients died. Among the 47 who recovered there were as many as 13 who suffered from pneumonia. The author concludes that the pneumonia complicating typhoid fever is seldom affected by vaccine treatment, and that when this treatment fails to benefit a case of typhoid fever it is usually because the patient is also suffering from pneumonia. Uncomplicated typhoid fever usually reacts satisfactorily to intramuscular injections of a staphylococcal vaccine, and the disappointing results obtained by other workers may in many cases be traced to the fact that they gave the vaccine by the intravenous, and not by the intramuscular route.

#### 65. Pepsin Solutions in Inoperable Prostatic Hypertrophy.

E. GRUNERT (*Zentralbl. f. Chir.*, December 3rd, 1927, p. 3088) confirms Payr's observations on the efficacy of injections of pepsin solutions in this condition, and he describes the case of a man in whom the pelvic floor was occupied by a non-inflammatory apparently malignant tumour. He gave three injections into the prostate of 10 c.cm. of a 2 per cent. pepsin solution, employing Payr's technique and allowing an interval of five days between each dose. The tumour contracted, and urination became normal. The patient, however, lost weight and died two years later. No necropsy was performed. Grunert suggests that this treatment might be of great value in affording relief in inoperable cases of prostatic hypertrophy or of malignant prostatic tumours.

#### 66. Somnifen in States of Agitation.

W. MARTINEZ and F. J. RODRIGUEZ (*Rev. de neurol., psiquiat., y med. leg. de Uruguay*, September, 1927, p. 2), who record ten illustrative cases of various forms of motor agitation treated by the soluble hypnotic somnifen (diethylallyl-barbiturate of diethylamine, came to the following conclusions. This drug, given intravenously in doses of 2½ to 4 c.cm., proved a powerful hypnotic in all cases of insomnia; it was also an effective sedative in motor irritability of alcoholic origin. It had absolutely no action on restlessness due to other causes such as manic-depressive psychosis, and it did not soothe post-oncetric states of depression or delirium even in alcoholic subjects. When given in the ordinary doses it was harmless provided that the blood urea did not exceed 50 cg. per litre and the cardiovascular system was healthy.

## Ophthalmology.

#### 67. Hereditary and Familial Optic Atrophy.

R. FAVIER (*Thèse de Paris*, 1927, No. 439), who records two illustrative cases in brothers, maintains that this condition—first described in 1871 by Leher, who collected 55 cases—is not so rare as is supposed. Hornum in 1900 obtained information about 74 families, which included 300 patients, of whom 131 submitted to medical examination. Other cases have since been reported by Klopfer, Buisson, Mathlon, and Helmsborger. In the great majority of cases the condition develops as retrobulbar neuritis, and appears to have no other cause but a familial and hereditary predisposition, being characterized not by its symptoms or ophthalmoscopic appearance, which resemble those of toxic amblyopia, but by its peculiar course. It rarely appears before the age of 12 or 13, nor after 30, except in women, in whom it develops between 41 and 49, about the time of the menopause. The youngest patient hitherto seen was a child aged 6 years, and the oldest were aged 52 and 67. Prodromal symptoms are exceptional. Visual disturbance occurs suddenly and develops rapidly in the course of the following four or five weeks, when it becomes more or less stationary. Sometimes the course of the disease is slower, lasting six to twelve months, or it may be rapid, producing almost complete blindness in a few days. Such cases, however, are exceptional. The affection is always bilateral, although both eyes are not always affected to the same extent or at the same time. The results of ophthalmoscopic examination vary according to the stage of the disease when it is made. During the progressive period comparatively little is to be seen; later, however, signs of partial atrophy develop. General disturbance may occur in the form of migraine, vertigo, vomiting, and sometimes epileptic attacks. The prognosis should be guarded, though it is not invariably hopeless. All treatment has hitherto proved ineffective.

#### 68. Arterial Spasm and Occlusion of Branches of the Retinal Artery.

H. P. WAGENER and J. F. GIPNER (*Amer. Journ. Ophthalmol.*, September, 1927, p. 650) describe five cases of spasm of a branch of the retinal artery. In two of the cases the affected branch was completely obliterated beyond a certain point and quite invisible. While under observation the artery opened up, refilled with three progressive pulses, and became normal, vision being completely restored. In both patients early signs of hypertension were noted, and in one symptoms of the Raynaud type had been detected. This patient complained of occasional short periods of blindness on various occasions over a period of years and involving part of the visual field. In the other cases there was permanent loss of vision, and on examination the affected artery appeared as a white cord. The authors consider that in these cases thrombosis of the blood occurred at the time of the arterial spasm or immediately following it.

#### 69. Bilateral Pre-papillary Vascular Loop.

A. M. YUDKIN (*Arch. Ophthalmol.*, September, 1927, p. 474) describes a case of bilateral pre-papillary loop of the retinal artery. In both eyes the central artery of the retina divided on the disc into two main branches. From the lower a spiral loop protruded into the vitreous, took a sharp turn, and returned to the upper temporal edge of the disc after making three spiral coils. The other vessels were normal. The slit-lamp examination revealed no remnants of the hyaloid arterial system. These phenomena have been reported from time to time, but it is very rare for the condition to be identical or even present in both eyes. With regard to the etiology, it is now held that the condition has nothing to do with either an inflammatory process or with the embryonic remains of the hyaloid artery, but is rather an excessive development with exaggerated tortuosity of the normal arterial system.

## Obstetrics and Gynaecology.

#### 70. Blood Transfusion in Obstetrics.

IN order to obviate the use of stabilized blood in bulk with its contained anticoagulants (such as sodium citrate), which are toxic in large doses, LÉVY-SOLAL and A. TZANCK (*Presse Méd.*, December 10th, 1927, p. 1505) have designed a simple apparatus by means of which a number of donors may be successively utilized at the one operation. The authors report twenty-six obstetrical and gynaecological cases in which this procedure was most beneficial and no fatalities occurred. These cases included post-partum haemorrhages, abortions complicated with haemorrhage, obstetrical shock, placenta praevia, acute

anemias of the pernicious type, and extrauterine pregnancies; in some of them artificial serum had been employed without benefit. The authors emphasize the importance of choosing the right moment for transfusion, and state that in all varieties of severe haemorrhage there are three distinct phases: (1) the stage of tolerance, in which the symptoms are not very apparent; (2) the phase of critical threshold, marked by an abrupt or progressive falling of the general state; and (3) the phase of asthenia or collapse, characterized by an imperceptible pulse and an absence of arterial tension. Preparations for the transfusion should be made on the first appearance of disquieting symptoms, and the operation be performed when progressive acceleration of the pulse and respiration occur. A description of the technique is given, whereby large amounts of pure blood can be transfused with the maximum of control and safety. As much as two litres may be necessary, and the authors' rule is to inject as much blood as has been lost. Their twenty-six cases included six of profuse bleeding during labour, seven of haemorrhage after abortion, three of shock following loss of a moderate amount of blood, three of placenta praevia, two of severe anaemia in pregnancy, and five of extrauterine gestation.

#### 71. Insulin in Gynaecological Conditions.

ACCORDING TO E. VOGT (*Zentralbl. f. Gynak.*, November 25th, 1927, p. 3034) insulin exerts important influences on the activity of the endocrine glands, especially the ovaries. Injections of insulin have been found by Vogt to be effective in treatment of certain cases of "ovarogenous bleeding"—that is, cases of menorrhagia or metrorrhagia attributable, in the absence of morbid uterine conditions, to ovarian dysfunction. Moderate doses given twice daily before the morning and evening meals are recommended, and are said to be effective usually within two or three days. In two cases of wasting without discoverable organic disease a course of insulin injections in small doses led not only to a large gain in weight but also to a return of the menses. The first patient, a nullipara aged 35, had lost 40 lb. in weight and had had amenorrhoea during six months; she regained her lost weight with seventy-two days' insulin treatment and began to menstruate regularly. The second patient, an unmarried woman aged 23, in seven weeks regained 11 lb. in weight and menstruated for the first time for two years. Further evidence pointing to a connexion between insulin and the ovary is perhaps found in successful insulin therapy of hyperemesis gravidarum, which has been regarded as a consequence of ovarian hypofunction, and which in the experience of certain observers has been favourably influenced by injection of ovarian extract. Sterilization of female animals by injections of insulin has been accomplished by Vogt and others; injections or implantations of ovarian extract or substance from gravid animals had the same effect. Vogt finds that the effect of insulin given to non-diabetic females shows a constant variation with the menstrual cycle. The maximum diminution of the blood sugar was obtained during the last eight days before menstruation and during menstruation; after this period the effect of insulin became rapidly less, and remained at a minimum level throughout the first half of the intermenstruum. These findings, which have an obvious practical importance in the treatment of female non-diabetics by insulin, are compared with those of Frank and of Fels, who determined that the concentration of ovarian hormone in the blood was at its highest ten days before menstruation and remained at a very low level during the first ten days of the intermenstruum: apparently the ovarian hormone content of the blood and insulin sensibility take parallel courses in the menstrual cycle. During the latter half of pregnancy Vogt has found that the insulin sensibility remains high but constant; Frank found that the ovarian hormone in the blood from the fourth month of pregnancy onwards remained permanently at the level of twice the amount present before menstruation. He adds that with increasing knowledge of the action of insulin it becomes more evident that its action is not specific, but is complex, pluripotent, and related to that of ductless glands other than the pancreas.

#### 72. Puerperal Septicaemia caused by *E. perfringens*.

R. PALAZZO (*Rev. Sud-Am. de endocrinol., immunol. y quimioter.*, October, 1927, p. 775), who records an illustrative case following criminal abortion, states that though puerperal septicaemia has formed the subject of numerous communications, especially in France and Germany, it has not received the attention it deserves, as it is much more frequent than is supposed. Puerperal infection with development of gas in the uterine wall during life was described by Dohrn in 1872 before the anaerobic flora were known, but the nature of the process remained obscure, and it was not until 1900 that Halban in Vienna made the first bacteriological study of gangrene of the uterus, in which he found Fraenkel's bacillus during life and gave the name of "septic emphysema of the uterus" to the condition. The most important studies have

since been made by Schottmüller (1910), Fraenkel (1924), Nürnberger (1925), and Lehmann (1926) in Germany, Brindeau and Macé (1900), Ballard (1918), and Telsier, Rivaller, and Theiral (1926) in France, and H. Thorn in England. According to Nürnberger this infection is commonest in cases of criminal abortion. The characteristic symptomatic triad due to an intense destruction of the red corpuscles consists in a yellowish-green coloration of the skin and sclerotics, changes in colour of the urine, which is at first yellowish red, then dark, and finally black, and dark red coloration of the blood serum. Spectroscopic examination shows the presence of methaemoglobin. The prognosis is bad, death being due to destruction of haemoglobin and endogenous asphyxia. The absorption of toxic products due to disintegration of the tissues may hasten the fatal termination.

#### 73. Surgical Intervention in Pelvic Infections.

A. H. CURTIS (*Journ. Amer. Med. Assoc.*, October 8th, 1927, p. 1191) discusses gynaecological problems and their treatment. He finds that in chronic leucorrhoea Skene's duct is as important a source of discharge as the uterine cervix and needs as much treatment. In chronic endocervicitis the establishment of thorough drainage is of great importance. He stresses the danger of repeated instrumentation of the uterus and also maintains that supravaginal hysterectomy performed even several days after diagnostic curetting is not an aseptic surgical procedure. In acute inflammation of the tubes operative treatment should be avoided. Curtis holds that a quiescent tubal infection is a self-limited disease, and that an operation is to be avoided except in the case of sequelae. With regard to diseased ovaries he thinks that less radical surgery is required in gonococcal cases than in those of tuberculous or streptococcal origin.

#### 74. Serological Diagnosis of the Puerperium.

C. LIPPERA (*Il Policlinico, Sez. Prat.*, November 14th, 1927, p. 1655) has tested the medico-legal value of serological examination in a number of puerperal women. It has been suggested that in the puerperium some milk passes into the blood and, acting as a heterogeneous protein, excites the formation of agglutinins, which in their turn will cause agglutination when mixed with prepared serum. The author found that with two exceptions the test was positive up to eleven months after parturition. It was found positive in a woman who brought forth a macerated foetus at seven months and in a woman eight months pregnant.

#### 75. Vertebral Deformity and Cardiopathy during Pregnancy.

P. KLEIN (*Arch. f. Gynak.*, September 1st, 1927, p. 653) draws attention to the need of surveillance during pregnancy of women with severe kyphosis and scoliosis; in addition to pelvic deformity morbid conditions of the heart are present which may have serious or even (as in two cases here described) fatal consequences. The "cor kyphoscolioticum" is associated with typical post-mortem findings of muscular degeneration, well marked hypertrophy of the right ventricle, and little or no alteration of the valves. Strain is thrown on the heart by (1) the compression of one lung by vertebral deformity and compensatory emphysema of the other, (2) impediment of thoracic breathing by ankylosis of the ribs, (3) difficulty of cardiac expansion owing to narrowing of the thorax. Women with advanced kyphosis and scoliosis are subjected to increased cardio-vascular strain from the earliest months of pregnancy and during each of the stages of labour. Klein describes sixteen cases and alludes to 103 others, in the majority of which grave signs of cardiac embarrassment occurred in the earliest stages of pregnancy. He thinks that when signs of decompensation have appeared before pregnancy, or when medical treatment is not speedily effective in cases in which cardiopathy is noted during the early months, induction of abortion is indicated. When the patient is first seen with marked signs of cardiac trouble during labour it is probably wisest to perform Caesarean section; this is the best means of eliminating the muscular labour of parturition, and has the advantage that by a simultaneous Porro's operation the patient may be spared the dangers of the puerperium and protected from the risks of subsequent conception.

#### 76. Respiratory Emphysema in Labour.

G. A. GORDON (*Amer. Journ. Obstet. and Gynecol.*, November, 1927, p. 633) reports two cases of respiratory emphysema as an unusual complication of labour, and reviews 130 previously recorded. Both his patients were healthy young primiparae in whom labour was somewhat prolonged, but the pains and straining were no worse than usual. In the first air crepitation with slight tenderness developed subcutaneously over the face, neck, and chest to the nipple level, eventually spreading to the parietal scalp, with entire disappearance by

the fifth day. In the second an area of emphysema extended from the infraclavicular space to the zygomatic arch on the right and to the lower jaw and trapezius on the left; by the fifth day it was present only just above the right clavicle, and had entirely disappeared by the tenth day. No predisposing cause could be discovered in the first case, while in the second the fact that the patient had had resection of two ribs for empyema in childhood may have been a determining factor. The clinical course of both was uneventful. The condition usually occurs during the second stage, but may arise in the first; frequently it is not noticed until after delivery, and may originate in any part of the air passages. Its etiology and pathology are not known. The prognosis is good and treatment is expectant, rapid delivery being indicated for steadily increasing emphysema or for symptoms of respiratory distress.

## Pathology.

### 77. Inheritance of Susceptibility to Malignant Tumours.

CLARA J. LYNCH (*Journ. Exper. Med.*, December, 1927, p. 917) has already adduced evidence that susceptibility to spontaneous tumours in mice is inherited. She has now performed a series of experiments to determine whether susceptibility to tumours induced by tar is also inherited. Two strains of mice were chosen: (1) an agouti strain having an incidence of spontaneous lung tumours of 6.73 per cent., and (2) an albino strain having an incidence of spontaneous lung tumours of 37.04 per cent. Thirty mice of each group were painted on twelve different regions of the body with tar extract; each region was painted four times, the total treatment lasting four months. The incidence of lung tumours in the agoutis was 22 per cent., in the albinos 85 per cent. The effect of the tarring had therefore been to raise the incidence of lung tumours considerably in both groups of mice. The agoutis had been crossed with the albinos, and 35 of the F1 generation were tared; after six months, when the surviving animals were killed, the incidence of lung tumours was 79 per cent.—that is, nearly as high as in the pure albino mice. Males of the F1 generation were then back-crossed with females of the albino strain, and the offspring tared; the incidence of lung tumours in these mice was 81 per cent., or about the same as in the pure albinos. The same males of the F1 generation were also mated with females of the agouti group; 39 offspring, all agoutis, resulted and were tared, the incidence of lung tumours being 39 per cent.—that is, greater than in the pure agoutis, but considerably less than in the albinos. The author concludes that there is little doubt that susceptibility to tumours induced by tar is inherited. It would appear that at least one factor governing susceptibility is dominant, for the F1 generation when back-crossed with the albinos gave approximately the same rate of tumour incidence as the pure albinos; on the other hand, the back-cross with the agoutis gave an intermediate result, indicating that probably more than one factor is involved.

### 78. The Etiology of Localized Oedemas.

J. CARLES (*Journ. de Méd. de Bordeaux*, November 25th, 1927, p. 847) draws attention to the fact that a localized oedema of cardiac or nephritic origin is usually related to a previous trauma. He mentions one case in which a previous fracture determined the site of oedema in a nephritic. In another case erysipelas was the factor which started an oedema of the face only. In cases of unilateral hydrothorax a previous pulmonary lesion, such as pleurisy or tuberculosis, is nearly always to be found. As an explanation the author suggests that in accordance with a general law by which microbes and poisons are attracted to the seat of a lesion a special aptitude is conferred on the tissues to detain locally such substances as chlorides and sodium. Or it may be that trauma has the effect of damaging the osmotic power of the capillaries or modifying their vasomotor functions.

### 79. Modification of Tuberculous Lesions by the B.C.G. Vaccine.

P. P. DWIKOFF and L. P. MASOUROWSKI (*Ann. de l'Inst. Pasteur*, November, 1927, p. 1194) vaccinated 17 guinea-pigs with the B.C.G. vaccine. The doses used were very small and were administered by the mouth, subcutaneously, or by intraperitoneal injection. The animals were subsequently inoculated with a very small dose of virulent tubercle bacilli, apparently by the same route as that used for vaccination. All the guinea-pigs except four died in from three weeks to three months; the four exceptions lived from four to seven and a half months. At necropsy the lesions in the guinea-pigs were found to be distributed throughout the usual organs,

but histological examination revealed that the tuberculous process was often advancing only slowly or was actually retrogressing. Fibrous tissue was abundant, caseation was not very marked, and in some animals actual calcification was seen. The guinea-pigs that survived for some months showed actual cavities in the lungs, together with calcareous masses. The authors conclude that in animals vaccinated with the B.C.G. strain and subsequently infected with virulent tubercle bacilli the lesions tend to be sclerotic, particularly those in the lymphatic glands and liver. The alteration in the course of the disease, however, is not sufficient to prevent death.

### 80. Effect of Sodium Salicylate on the Heart.

A. M. MASTER (*American Heart Journal*, December, 1927, p. 180) has studied the effect of sodium salicylate on normal individuals in order to determine whether the use of this drug in rheumatic fever produces some of the electro-cardiographic changes observed in that disease. These include prolongation of the P-R interval, from an almost imperceptible depression of conduction to dropped beats; partial or complete heart-block; alteration in rhythm (sinus arrhythmia, sino-aortic block, nodal rhythm, premature beats, paroxysmal tachycardia, auricular fibrillation, and flutter) and changes in the QRS group and S-T transition interval. Master gave full medicinal doses (that is, 60 to 120 grains of sodium salicylate in the twenty-four hours) to thirteen patients in hospital, until toxic symptoms occurred. The patients' hearts and lungs and blood pressures were previously normal. Electro-cardiograms were taken before and after the salicylate administration. The drug had no effect on the pulse rate, the electro-cardiographic tracing showed no abnormality, and no evidence was obtained that the drug affected normal heart muscle. The author concludes that since in rheumatic fever electro-cardiographic changes are almost invariably present, and sodium salicylate has been shown to be incapable of causing such alterations, they must be due to the disease alone.

### 81. Transmissible Toxicogenicity of Streptococci.

M. FROBISHER, jun., and J. H. BROWN (*Bull. Johns Hopkins Hosp.*, September, 1927, p. 167) cultivated non-toxicogenic, non-scarlatinal streptococci, and strains of *B. coli*, *B. prodigiosus*, *B. subtilis*, and *S. albus* in mixed culture with toxicogenic scarlatinal streptococci, and recovered them in pure culture. Two non-scarlatinal streptococci were then found to have acquired temporarily a definite toxicogenicity giving rise to a toxin which was neutralized by antiscarlatinal serum. The other organisms did not acquire any toxicogenicity. The authors also found that non-toxicogenic streptococci might acquire a toxicogenicity from sterile Berkeley filtrates of the scarlatinal type, although the toxicogenic powers so acquired were in general less marked than those acquired from the mixed cultures. This is taken to suggest the existence of a filterable second factor associated with the scarlatinal streptococci.

### 82. Pathogenesis of Tuberculosis in Adults.

F. HARBIZZ (*Norsk Mag. f. Lægevidensk.*, November-December, 1927, p. 892) publishes post-mortem findings during the ten-year period (1916-25) at the Rikshospital in Oslo, where 1,882 complete examinations were made of persons over the age of 15. Among them there were 239 cases in which death was due to tuberculosis, pulmonary tuberculosis being responsible for 141 deaths, and other forms of this disease for 98 deaths. Among the 141 cases of fatal pulmonary tuberculosis there were 35 in which the necropsy findings proved, or suggested, that the disease was caused by infection in childhood. Among the 98 cases of other forms of tuberculosis there were as many as 65 in which the disease could be traced to infection in childhood. Thus 100 of a total of 239 fatal cases of tuberculosis could be regarded as auto-reinfectious. This proportion (42 per cent.) of auto-reinfections was probably an underestimate, as some cases of old infections in childhood may have been overlooked. When the persons dying between the ages of 16 and 30 were considered by themselves it was found that among the 478 necropsies made on persons of this age there were as many as 143 (30 per cent.) whose deaths were caused by tuberculosis. At the necropsies of these 143 cases signs were found of an old infection in childhood in as many as 79 (55 per cent.). The author concludes that with regard to tuberculosis in structures other than the lungs the disease in adult life is usually the result of spread of infection from a focus which developed in childhood. He is more cautious in his judgement with regard to fatal cases of pulmonary tuberculosis in adults, as it is comparatively difficult to judge from the clinical history and the post-mortem findings between the possibilities of a new, an exogenous, and an endogenous infection from an old focus.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 83. Pulmonary Tuberculosi as a Sequel to Pleurisy.

O. SCHJEL (Norsk Mag. f. Lægevidensk., November-December, 1927, p. 913) has investigated the subsequent fate of patients suffering from pleurisy, with special reference to the development of tuberculosi. For the sake of comparison he quotes the Swedish statistics of Köster and Allard, whose 514 cases of primary pleurisy were observed for one to twenty-eight years after the pleurisy. They found that 47.7 per cent. subsequently developed tuberculosi, and that 22.4 per cent. died of it, most of the cases of tuberculosi developing within the first five years after the pleurisy. Schjel's cases of pleurisy were treated at the Ullevaal Hospital in Oslo in the ten-year period (1916-25). More than two-thirds of the total of 956 patients were between the ages of 11 and 30, the period between 16 and 25 being that at which the pleurisy was most common. In the spring of 1927 information was obtained as to the subsequent fate of 812 of these 956 patients, and it was found that 22.4 per cent. had developed tuberculosi, mostly of the pulmonary form, and the mortality was 9.9 per cent. Commenting on the fact that the proportion of post-pleurisy cases of tuberculosi was much lower in his own material than in Köster's, Schjel suggests that the after-treatment which his patients received was better. He found that the most dangerous years after an attack of pleurisy were the first three or four.

### 84. Diminished Secretion of Sweat in Heart Failure.

It has been observed that when cardiac patients with oedema are confined to bed and given appropriate treatment increases in the secretion of sweat and of urine often run parallel; the fact that these patients stand heat, whether climatic or in the form of physical treatment, badly has also been ascribed to imperfect regulation of body temperature due to defective sweat secretion. E. KAUF and E. ZAR (Wien. klin. Woch., November 10th, 1927, p. 1405) found by microscope observation that in normal persons perceptible droplet secretion of sweat is confined during mental and physical rest to a few areas, including the finger-pads of the terminal phalanges, where it is continuous. In the other method employed in studying the secretion of sweat the fingers were pressed for two minutes on to filter paper which had previously been impregnated with 1 per cent. silver nitrate solution and dried; the sodium chloride in the sweat droplets converted the silver salt into the chloride and showed on exposure to light as a series of black spots. Repeated observations on a number of patients with cardiac disease gave the following results. In 15 out of 17 cases with compensated valvular lesions the secretion of sweat was normal, while in all 27 cases of valvular lesions with failure of compensation, myocardial degeneration, and enlargement of the liver the secretion of sweat was much diminished or absent; in most cases this persisted even when other symptoms had improved. The authors do not consider that the failure of secretion is initiated by local peripheral conditions, such as lack of oxygen or accumulation of carbon dioxide, or local anaemia, since the secretion was normal in three cases of congenital heart disease with marked cyanosis, and sweating occurs under hot-air treatment in an arm made anaemic by Esmarch's method. They conclude that the phenomenon of deficient sweat secretion in cases of the type described is closely connected with the stagnation of fluids in the tissues by some mechanism which has not yet been explained.

### 85. Malignant Granulomatosis.

C. LAUBRY, G. MARCHAL, and R. LIÈGE (Rev. de Méd., 1927, No. 6, p. 695) think that "Hodgkin's disease" is a misnomer for this condition. They report the case of a man, aged 23, who had marked emaciation, extreme pallor, profound cachexia, and exophthalmos. Multiple adenitis was noted in both axillae, on both sides of the neck, in the left supraclavicular region, and in the groins. He exhibited a mediastinal syndrome of presternal and intercostal pain and bilateral phrenic neuralgia, percussion over the entire thorax, and especially over the sternum, being very painful. The spleen and liver were enlarged, but the other organs were normal. Diffuse and lancinating headache, most marked in the supraorbital regions, was present. The blood showed a leucocytosis and a complete absence of eosinophils, the pleural and cerebro-spinal fluids a lymphocytosis, while the second of three Wassermann tests was positive. Pruritus and syphilitic stigmata were absent. In spite of treatment

the patient died two months later, and at the necropsy a soft white mass, which had eroded the first cartilage and the second rib, was found at the first right intercostal space. The liver, spleen, and ganglia were enlarged. Microscopically the ganglia showed a marked development of fibrous connective tissue in which were numerous new blood vessels. Eosinophils were very rare, but many giant cells of Sternberg, a histological characteristic of this disease, were seen, some showing karyokinesis. The liver revealed a cirrhosis marked by a very rich vascularization, and a lymphocytic granulomatous infiltration. The new blood vessels were gorged with red cells, causing minute haemorrhages. In an abdominal metastatic nodulo many cells of Sternberg were seen. The authors remark that the absence of pruritus, and of eosinophils in the blood, two symptoms of great diagnostic value, is not exceptional, and that variations in the Wassermann reaction are found also in other diseases. They believe that inflammation plays an important part in the genesis of this malady, but that its malignant character is necessarily due to the development of malignancy of the sarcomatous order. The erosion of the sternum, the great formation of new blood vessels, the karyokinesis in the Sternberg's cells, and the microscopic embolisms, are strong arguments in favour of this theory, which is widely held.

### 86. Diphtheria in Chicago.

H. N. BUNDESEN (Public Health Reports, October 7th, 1927, p. 2447) states that during the first seven months of 1927 the number of cases of diphtheria in Chicago was greater by 50 per cent. than that recorded for the corresponding months of 1926; the death rate also was nearly doubled, partly in consequence of a corresponding increase in morbidity, but the major factor was a marked rise in the case fatality rate of the disease—namely, 12.8 per cent. during the first seven months, as compared with 7.4 per cent. in 1926 and 8 per cent. in 1925. Clinically the type of diphtheria in Chicago, as in Germany, was more malignant than for several years past. The severe toxic and septic cases often failed to respond to treatment, even when antitoxin was given early and in usually adequate doses. The greater prevalence of diphtheria in Chicago during 1927 was not due to infection by milk, food, or epidemic foci, but represented a generalized increase in the endemic rise.

## Surgery.

### 87. Spontaneous Amputation of Appendix.

R. J. KIRKWOOD (Boston Med. and Surg. Journ., November 24th, 1927, p. 982) describes a case of spontaneous amputation of the appendix in a woman, aged 38, who was admitted to hospital with a diagnosis of chronic appendicitis. For some years she had had pain in the right iliac region of a mild character, with some nausea; about four weeks before admission there had been a more severe attack. Deep palpation showed some tenderness but no spasm; and the patient was constipated; while under observation for four days the temperature never rose above 99.5°, and the blood and urine showed no abnormality. At the patient's request an operation was undertaken. The caecum was found free and there were no adhesions. The appendix, which was 2 cm. long, was found lying entirely free from any connexion with the caecum. It was slightly injected, closed at both ends, and attached by a mesentery. The pathological report showed a chronic and healing appendicitis. Convalescence was rapid and without incident.

### 88. Surgical Treatment of Pruritus Ani.

C. E. CORLETTE (Med. Journ. of Australia, October 22nd, 1927, p. 580), reasoning from the success following division of the nerve supply in irritable ulcer of the leg, adopted a similar procedure in cases of pruritus ani, with resulting cure of the condition. Under local anaesthesia by infiltration with novocain and adrenaline of the anus and surrounding skin for two and a half inches a straight bistoury is inserted painlessly at four spots far enough from the anus to avoid infection; two of these are lateral, one is behind, and one in front of the anus; the point of the knife is directed up to and beneath the anal margin, undercutting without perforating the skin around the anus so as to sever the nerve filaments passing towards the skin from the subcutaneous tissue. By inserting the knife at all four points it is possible by a

sweeping movement to separate completely the skin near the anus from the underlying fat. It is not necessary or advisable to separate the skin out to the circumference in which the points of insertion lie; all that is needed is that the anal margin shall be undercut, the punctures being effectively sealed with collodionized gauze. Corlette claims that this method is less severe than the other open operations described and which are more liable to infection. Where the area of pruritus is extensive he advises a series of operations so that the field should be undercut piecemeal, area after area being treated at intervals of about a fortnight. He emphasizes the importance of getting the knife beneath the area at the orifice of the anus, and advocates a second attempt if the first is not completely successful.

#### 89. Closure of Bladder following Prostatectomy.

W. E. LOWER (*Journ. Amer. Med. Assoc.*, September 3rd, 1927, p. 743) gives a preliminary report of his experience of fifty prostatectomies, in most of which the bladder was closed at the time of operation, a rubber tube being inserted suprapubically for a few days in the remainder. With a catheter in the urethra a dot-and-dash catgut (No. 0) suture is passed from the bottom of the cavity from which the prostate has been removed and along its walls on each side up through and including a small margin of mucous membrane, bringing the walls into apposition, the suture being inserted above and below the catheter. The catgut is cut short and the mucous membrane trimmed to facilitate healing. A good sized catheter with two eyes should be used, and any spurting vessels are tied before the sutures are closed. By this means, it is claimed, haemorrhage can be absolutely controlled. The cut edges of the bladder are sutured, care being taken that there is no protrusion of the mucous membrane, and a rubber cigarette drain is placed in the space of Retzius. The danger of stricture at the vesical neck may be obviated by dilations for a short time, and the use of too heavy catgut, especially chromic, should be avoided, since the knots may form a nucleus for the formation of stones. Lower claims that with this technique convalescence is shortened and the incidence of fistula reduced to a minimum.

#### 90. Cancer in the Young.

G. GULDBERG (*Norsk Mag. f. Laegevidensk.*, November-December, 1927, p. 1131) states that during the period of twelve years specimens of 4,612 cases of cancer have been collected at the pathological institute attached to Oslo University; 157 of those specimens were taken from persons between birth and the age of 30, 112 being female and 45 male, and 11 children under 15 years of age. The disease occurred most frequently in the female genitalia, which supplied 53 cases; next came the digestive organs (24 cases), the skin (19), testis (9), nose and its accessory sinuses, larynx, and ear (9), buccal cavity (6), appendix (10), and other situations, as well as recurrences and metastases (25 cases). There were two cases of carcinoma of the oesophagus, in men aged 20 and 28 respectively; as the second patient had drunk lye at the age of 5 or 6 his case was probably one of cancer developing in scar tissue caused by the lye twenty-two years previously. The ten cases of gastric cancer included one of adenocarcinoma in a man, aged 21, in whom the disease had a rapid course terminating fatally in twelve weeks. The necropsy showed cancer of the pylorus with extensive metastases in peritoneum and liver. The eleven cases of intestinal cancer included one of carcinoma of the ileum in a girl aged 18, and three cases of carcinoma of the caecum associated with caecal tuberculosis. The cutaneous cases, which included one of carcinoma of the leg in a boy aged 12, following neurodermatitis of many years' duration, showed that the skin in childhood and youth does not remain unaffected by irritants which have a carcinogenic effect in later life.

#### 91. Sympathectomy in Angina Pectoris.

D. DANIELOPOLU (*Bruxelles-Médical*, November 13th, 1927, p. 33) asks why permanent lesions such as disease of the coronary arteries should give rise at times, though not invariably, to spasmodic anginal attacks, which may occur in the absence of coronary disease. Huchard collected no fewer than eighty hypotheses to account for the pain which Daniélopou attributes to myocardial fatigue and pressor reflex. Elimination of the pressor reflex by section of the sympathetic cures the angina. The operation recommended by Daniélopou has now been employed several times successfully, and, unlike other surgical procedures for the cure of this complaint, is not fatal. Usually it is performed on the left side of the neck, and in two stages if required; but often a further operation is not necessary. Under the term "pressor reflex" the author includes raised blood pressure, increased cardiac force and pulse rate, and probable vasoconstriction of the coronary arteries. The aim of the opera-

tion is not so much the relief of the pain as the prevention of the conduction of the pressor reflexes along the cardio-aortic nerve fibres; the contrifugal nerve fibres of the heart are untouched. In the first operation the cervical sympathetic is cut above the inferior cervical ganglion, the vertebral nerve, and the branches of the cervical vagues entering the thorax. After the operation the attacks cease, recur a little later owing to cicatricial irritation, and then gradually diminish. So far death has not followed this operation.

#### 92.

#### Diverticulitis.

A. CANNON (*The Caduceus*, July, 1927) cites a reference to Telling's disease (*JOURNAL*, 1927, vol. i, p. 344) and suggests a scheme to link the anatomy of the condition with the pathology and clinical manifestations. He describes four clinical groups—namely, inflammatory, obstructive, fistulous, and pelvic—and emphasizes the importance of a radiological examination to distinguish it from such conditions as carcinoma, sigmoiditis, hyperplastic tuberculous, syphilis, and pelvic conditions, particularly in the female. He appends notes on twelve clinical cases collected from the literature and supplies a bibliography of 349 references.

## Therapeutics.

#### 93.

#### The Use of Iodine in Thyroid Disease.

C. G. HEYD (*Boston Med. and Surg. Journ.*, December 8th, 1927, p. 1075) distinguishes three types of thyroid disease: one characterized by an increase of secretion with varying clinical reactions, the so-called toxic adenoma; one by a change in the character of the secretion and representing a dysfunction with hyperthyroidism, the so-called Graves's disease; and the third by a decrease of secretion, the so-called colloid goitre or myxoedema. Thyroxine, discovered and isolated by Kendall, contains 65 per cent. of iodine, and every cell in the body requires it in order to function properly. The thyroid gland must obtain 22/100 mg. of iodine per day, and all thyroid activity is dependent upon the amount of iodine present in the gland, the blood stream, and in the body tissues. Thyroxine is manufactured in the cells of the acini, and any excess over the physiological requirement is stored in the colloid material. If the cells fail to elaborate this substance in sufficient amount, the colloid begins to lose its thyroxine and to contain less and less iodine. If more thyroxine is elaborated than is necessary, the excess passes into the blood stream and the colloid material is partially or wholly unable to store iodine. After discussing the various conditions of hyper- and hypo-thyroidism, Heyd asserts that iodine is pre-eminently useful in goitre prophylaxis, and that it is immaterial how it is administered or in what form, providing that the dose is small and the treatment intermittent. It is useful in stabilizing function in colloid goitre, but care should be taken to eliminate adenoma, which is infrequent before the age of 20. It is distinctly indicated as a preventive measure, either in or out of regions of high goitre incidence, during pregnancy and lactation, and the menopause; for a short period of time, but without a gap, as a pre-operative measure in Graves's disease; and as a post-operative measure after all types of goitre operations. Its value in adenomata is variable, but there is the definite danger of causing hyperthyroidism in non-toxic adenomatous goitres. When used outside of these restricted indications, there is a risk of producing an iodine hyperthyroidism which is fixed, progressive, and dangerous.

#### 94.

F. SCHÜRER-WALDHEIM and F. WINDHOLZ (*Deut. Zeit. f. Chir.*, December, 1927, p. 111) record their observations on 18 cases of Graves's disease, 17 of which were in women and one in a man, who were treated with iodine in the form of Lugol's solution in doses of 10 drops two or three times a day. In every case a remission of the symptoms occurred, as shown by disappearance of palpitation, restlessness, sweating, tremors, and diarrhoea. The goitre became harder and the pulse slower. Operation, which consisted in extensive bilateral resection of the thyroid, was well borne, and there was no post-operative shock when administration of Lugol's solution was continued for six or seven days. Histological examination also showed that the morphological appearance of the thyroid was affected by administration of iodine. The state of the goitre after iodine treatment was found to depend principally on its original condition; the change was first shown by hyperplastic forms being replaced by an inactive parenchymatous or colloid goitre. Atrophy and severe degenerative changes in the epithellium also occurred. In place of the watery colloid a thick colloid appeared, indicating a drying up of secretion. Infiltration of lymphocytes was

not with in connexion with the atrophic and degenerated cells. No direct relation, however, could be found between the degree of morphological changes and the clinical condition in the glands treated with iodine.

#### 95. Synthalin Treatment of Diabetes in Children.

H. HIRSCH-KAUFFMANN and A. HERMANN-TROSIEN (*Jahrb. f. Kinderheilk.*, November, 1927, p. 47), as the result of their observations on diabetes in children treated with synthalin, come to the following conclusions. (1) A course of synthalin must be started with the smallest doses possible; cholagogue drugs should be given at the same time as synthalin so as to prevent occurrence of unpleasant symptoms such as abdominal pain, vomiting, and diarrhoea. (2) The interval of twenty-four to thirty-six hours between the doses required by Frank may be reduced to sixteen hours without any bad effects. (3) There is no hard-and-fast line between an effective and a toxic dose, but not more than 1.5 mg. of synthalin per kilo of body weight should be given. (4) The effect of synthalin treatment is much slower in children than in adults. The omission of insulin treatment, therefore, should not begin until the second course. (5) Glycosuria and glycaemia are distinctly diminished by the treatment. (6) A combination of insulin and synthalin treatment leads to a considerable reduction in the amount of insulin required. (7) Synthalin treatment is contraindicated in coma and the precomatose stage, as well as in very young children and those considerably under weight.

#### 96. Calcium Therapy in Functional Nervous Disorders.

C. C. GAULT (*Minnesota Med.*, December, 1927, p. 759), recognizing the similarity between animals during calcium starvation and patients suffering from the less severe functional nervous disorders, and arguing that such symptoms might be the expression of a disturbed calcium ratio resulting in general cellular irritability, and a lowered calcium retention, treated eighteen patients with calcium for from three to six months. After a thorough physical examination to exclude the presence of organic disease each patient was given orally the equivalent of 20 grains of calcium lactate four times daily, an intravenous injection of calcium chloride to one patient being discontinued as being no more beneficial than when the calcium was given by the mouth. The results were quite uniform, as within twenty-four to forty-eight hours a sensation of mental and physical well-being was experienced, and all feelings of fatigue, nervousness, and apprehension disappeared. Appetite and sleep also improved, and four patients had no recurrence of the dull occipital headaches from which they had frequently suffered. Gault considers that this series of cases shows the probability of a direct relationship between functional nervous disorders and calcium metabolism, which may be of value in dealing with the milder neuroses.

## Neurology and Psychology.

#### 97. Syndrome of the Corpora Quadrigemina.

M. R. CASTEX and A. F. CAMAUER (*Rev. oto-neuro-ophthalmol. y de cir. neurol.*, September, 1927, p. 121), who record four illustrative cases—in a man aged 53, a girl aged 12, a woman aged 33, and a man aged 24 respectively—state that this is an extremely rare condition, as Valobra in 1909 could find only 55 cases on record. The symptoms are as follows: paralysis of upward movement of the eyes; amblyopia; ocular palsies, which are usually symmetrical but may be asymmetrical; pupillary changes, of which absolute lack of response to all stimuli is the most frequent; auditory disturbance; cerebellar changes, shown by disturbance of co-ordination; bradyphasia; and, lastly, headache, vomiting, and psychical symptoms due to cranial hypertension. In the first of the authors' cases the necropsy showed an area of cerebral softening in the region of the corpora quadrigemina and grey substance surrounding the aqueduct of Sylvius, and in the second and third cases a small round-celled glioma was found in this situation. The fourth case did not come to necropsy.

98.

#### Cerebellar Localization.

J. A. BARRÉ (*Paris méd.*, October 8th, 1927, p. 265) discusses the value of Bárány's index-finger test in suspected cerebellar disease. The test is performed by placing the patient with his arm and forefinger extended on a level with his shoulder; his forefinger is placed against that of the observer, and he is then asked, with his eyes closed, to raise and lower his arm to the knee several times, coming back each time to the original position. In cerebellar lesions certain effects are observed. Thus, assuming that the cerebellar cortex has, for each segment of a limb, four centres, representing the four chief directions of movement, an irritative lesion

of one of these centres will result in the limb performing the opposite action. Thus in the case of irritation of the adductor centre of the forearm, the forefinger will be brought back abducted from the elbow; if the lesion is a paralytic one—for example, of the adductor centre—the patient is unable voluntarily to adduct his forearm, even when electrical stimulation is applied to the muscles. Barré, without impugning these results, nevertheless considers the test unreliable. He states that it is often found positive in vestibular disease, and, as many cerebellar affections exhibit only vestibular symptoms, the test may fail just when it is most needed. In cases, therefore, when the labyrinthine syndrome (nystagmus towards the side opposite to that in which deviation of the trunk and limbs is observed) is altered in any way—as, for example, by the direction of deviation of the limbs—cerebellar disease may be at once suspected, but a positive Bárány's sign should not be allowed to exclude the possibility of a pure vestibular condition.

#### 99. Hemiplegia Associated with Extensive Naevus and Mental Defect.

T. BRUSHFIELD and W. WYATT (*Brit. Journ. Child. Dis.*, July-September, 1927, p. 209), who had previously reported three cases of a syndrome comprising hemiplegia, extensive cutaneous naevus, and mental defect (see *Epitome*, August 27th, 1927, para. 178), report a fourth case in a male patient aged 17 years 8 months. The patient was a low-grade imbecile who from birth had presented naevus markings involving the right side of the face, right arm, chest and back, both legs and penis, leaving the abdomen free. The buccal mucous membrane was also involved. He could walk and run, but the left leg had a tendency to drag, and the right arm was paralysed and spastic. Only three similar cases, reported by E. A. Cockayne, F. Parkes Weber, and D. M. Greig respectively, are on record.

#### 100. Shyness and Schizophrenia.

F. A. HAMPTON (*Journ. Neurol. and Psychopath.*, October, 1927, p. 124) discusses the similarities and differences between shyness and schizophrenia, and suggests that in the former a normal instinct of self-assertion is inhibited by an abnormally active instinct of submission. In the schizophrenic the morbidly active instinct of self-assertion dominates the personality, but is inhibited, except in the later stages, by a normal instinct of submission. Hampton regards the shy person in general as suffering from a conflict between an urge to reach upwards to the normal level from the position of imagined inferiority and a deterrent fear of failure. He discusses this feeling of inferiority and also the general phenomena of shyness, and adds that here, as in other neuroses, the symptoms may represent the deformed fulfilment of a repressed wish. He agrees that suggestion, if carefully used, may benefit a shy patient, but insists that a more satisfactory method of treatment is to help him to recognize the source of the feeling of inferiority, and so to deal with it effectively.

## Obstetrics and Gynaecology.

#### 101. Pregnancy Complicated by Diabetes.

ACCORDING to H. P. A. SMIT (*Nederl. Tijdschr. v. Geneesk.*, November 26th, 1927, p. 2226) the association of diabetes mellitus with pregnancy is so rare that the earlier writers thought that conception could not occur in women suffering from diabetes mellitus. This view was subsequently shown to be incorrect, as about 5 per cent. of diabetic women become pregnant. The chance of fertilization is only slight, inasmuch as diabetes does not usually occur in young persons, and women with diabetes usually suffer from genital atrophy and inflammatory processes, such as vulvitis, vaginitis, cervical catarrh, and endometritis. There is only a comparatively small number of cases of pregnancy in diabetes on record. Offergeld, in 1908, was able to collect only fifty-eight examples, some of which did not have true diabetes. Von Noorden saw 9 cases of pregnancy among 240 women between 20 and 40, and Rosenberg had 7 cases among 111 patients. According to Offergeld, 50 per cent. of diabetic women who become pregnant die within two years of delivery. It is important, however, in the case of pregnant women with glycosuria to determine whether diabetes is really the cause, and an estimation of the blood sugar content is indispensable for this purpose. Smit regards it as reasonable to suppose that the prognosis is not so unfavourable under an appropriate treatment including insulin. Induction of abortion, therefore, is not justified, especially as the dangers of this procedure are much greater in a diabetic than in a normal woman. It is also possible that the current views regarding the prohibition of breast-feeding for diabetic women should be changed.

## 102. Detachment of the Normally Situated Placenta.

G. GUICCIARDI (*Riv. d'Ostet. e Ginecol. Prat.*, November, 1927, p. 421) describes a series of 22 cases of detachment of the normally situated placenta (accidental haemorrhage), in all but three of which the urine contained albumin. Of the three exceptional cases, in one there was a clear history of accident preceding the haemorrhage, and in one grave bleeding followed immediately spontaneous rupture of a hydramniotic membrane-sac. The series contained two primiparae only, and no more than five patients were less than 30 years old. There were four maternal deaths, one before and three within a few hours after delivery; in all the necropsy showed unusual softness of the uterine wall and an infiltration of the myometrium with blood, which extended as far as the peritoneum, and was most marked in the zone of placental attachment. Seven foetuses survived. Labour was completed eight times by accouchement forcé, twice by forceps delivery, eight times by podalic version and extraction, and three times by craniotomy of a dead foetus; one patient died undelivered. Guicciardi thinks, nevertheless, that in the grave cases coeliotomy with subtotal hysterectomy or Porro's operation is the only means of saving the mother's life; careful routine examination of the urine during pregnancy, early diagnosis, and early admission to hospital will improve the prognosis. The loss of life is ultimately caused less by the haemorrhage than by the underlying pregnancy toxæmia. In treatment it is wrong, except where the os is fully dilated, to rupture the membranes, which, by diminishing the intra-amniotic pressure, may increase the tendency to bleeding. Injections of pituitary extract or ergot, or gauze plugging before delivery, also favour haemorrhage, and are contra-indicated; morphine and chloral hydrate, on the contrary, are called for in some cases. It is recommended that the uterus and vagina be plugged with gauze after delivery, however effected.

## 103. Treatment of Retained Products of Conception.

J. L. WODON (*Strasbourg-Medical*, November 27th, 1927, p. 103) bases his treatment of retention of placental or membranous fragments on the three following assumptions, which he regards as proved. (1) From the fifth day of the puerperium the uterine cavity is invaded by vaginal organisms, including, in 38 per cent. of cases, streptococci. (2) The presence of placental remains is, even *in vitro*, an encouragement to bacterial growth. (3) So long as any part of the uteroplacental circulation remains behind, direct invasion of the maternal blood by intrauterine organisms is possible. Having emphasized the importance of careful examination of the placenta after delivery, the author recommends the following procedures. When fragments of membranes are retained immediate injections of ergotine or pituitrin (preferably the latter) should in most cases cause expulsion in two or three days. If they are not extruded, curetting should be performed before the fifth day in afebrile cases, but in febrile cases intrauterine douches should be begun early and continued till the sixth day. With retention of a cotyledon after instrumental delivery, manual removal should be performed at once under strict conditions of asepsis. If the delivery has been natural, the uterus should be curetted between the third and fifth day if expulsion has not occurred. If there is elevation of temperature or pulse, curetting should be performed at once. The author recommends the use of a cutting curette of large diameter, always gently manipulated so that no intrauterine grating sound is produced. He considers that the blunt curette commonly used cannot be relied on for the removal of small fragments, especially if there has been any endometrial inflammation.

## Pathology.

104. *B. paratyphosus* A Isolated from a Pig.

L. BROUDIN (*C. R. Soc. de Biologie*, December 16th, 1927, p. 1589) examined a pig that had died after an illness lasting one week and characterized by haemorrhagic diarrhoea. The main features at necropsy were broncho-pneumonia, necrosis of the liver, congestion of the intestine, and small ulcers in the caecum. Cultures from the bone marrow produced a coliform organism which gave the cultural, biochemical, and serological reactions of *B. paratyphosus* A. Injected subcutaneously in a dose of 4 c.cm. of a twenty-four-hours' broth culture it killed a wild boar in six days, after an illness marked by severe fever. In a dose of 1 c.cm. it killed a young pig in eleven days; this animal likewise developed high fever. From the bone marrow of both animals an organism was recovered similar to that injected, except that the agglutination titre was lower. Six months after its isolation it had become avirulent for young pigs, except in a dose of 20 c.cm., and its agglutination titre with a specific *B. paratyphosus* A serum had sunk even lower.

## 105. The Comparative Value of Renal Function Tests.

To determine the most reliable of the renal function tests in common use B. D. BOWEN (*Amer. Journ. Med. Sci.*, December, 1927, p. 769) made a study of fifty-two mild or suspected nephritics, employing in each the following determinations: the relation of the day and night urine volume and specific gravity, the blood urea nitrogen content, the phenolsulphonephthalein excretion, the urea concentration test (Maclean), the urea concentration index (J. F. McIntosh), and a modification of the urea concentration factor (Harrison). Patients having albuminuria, with or without casts, arterial hypertension, or oedema, were chosen; many suffered from diabetes also. Cases of renal lesions with functional impairment were purposely avoided. Bowen discusses the work and conclusions of many experimenters, and describes his own technique. His experiments showed that all tests were satisfactory, though some were more delicate and uniformly reliable than others. He believes that tests to determine the concentrating power of the kidney should be employed in all routine work. The urea tests corresponded better with the day-night urine volume ratio and specific gravity than with the phenolsulphonephthalein test or determination of the blood urea nitrogen, though the last two are useful for rapid diagnosis. Phenolsulphonephthalein tests are seemingly normal in about 50 per cent., and too low in 40 per cent. The urea concentration index (McIntosh) is a fairly dependable criterion. The author agrees with Maclean that any concentration of urea in the urine (second hour) that is below 2 per cent. is evidence of kidney insufficiency, and if the concentration exceeds 2.5 per cent. renal function is fairly efficient. The day-night urine volume ratio and the urea concentration test (Maclean) give a satisfactory estimation of renal function, but the blood uric acid test is valueless.

## 106. Serological Classification of Bacilli Isolated from Rhinoscleroma.

H. MEISEL and E. MIKULASZEK (*C. R. Soc. de Biologie*, December 2nd, 1927, p. 1495) have isolated bacilli of the Friedländer type from 77 per cent. of patients suffering from rhinoscleroma. High-titre agglutinating serums were prepared by the injection of rabbits with strains which had lost their capsules as the result of prolonged cultivation. Cross-agglutination and absorption tests were made, using non-capsulated bacilli as antigens. By this means it was found possible to classify the organisms into three types; other strains of Friedländer's bacillus isolated from non-rhinoscleromatous conditions provided four further types. Those results were confirmed by the complement fixation test (*ibid.*, p. 1498), which apparently can be used with both capsulated and non-capsulated strains. Of the strains isolated from patients with rhinoscleroma 64 per cent. fell into Type A, and gave similar biochemical reactions.

## 107. The Surface Tension of the Blood Plasma in Scarlet Fever.

ACCORDING to P. V. KISS (*Jahrb. f. Kinderheilk.*, January, 1928, p. 381), Traube and his collaborators, followed by Ehrlich and Bechold and Berczeller and Hetényi, have shown that an increase in the activity of toxins and bactericidal substances was usually accompanied by a diminution in the surface tension of their solutions. These results prompted the present author to investigate whether and in what degree the surface tension of the blood plasma was affected in scarlet fever. As the result of the examination of fifteen cases of scarlet fever in children, ten of which were uncomplicated while five had various complications, he came to the following conclusions: (1) In childhood the surface tension of the plasma shows more or less of a fall in the first week of scarlet fever. (2) In cases in which there is an uncomplicated recovery this fall of tension gradually disappears, and in a large percentage of the cases the normal value is restored on complete recovery from the attack. (3) If a complication occurs, and often before it has actually appeared, there is a fresh fall in the surface tension. (4) The fall of tension occurs at the same time as the rise in the fibrinogen value.

## 108. The Existence of Melioidosis in Cochín China.

R. PONS (*Ann. de l'Inst. Pasteur*, December, 1927, p. 1338) records two cases of melioidosis in Cochín China. From the first case he succeeded in obtaining a positive blood culture. The causative organism of the disease, first described by Whitmore, and later named *B. whitmori* by Stanton and Fletcher, is a slightly motile bacillus closely resembling the glanders bacillus. In man it gives rise to a disease which may simulate either cholera or typhoid fever, or may assume a chronic suppurating type. It is probable that the disease is endemic in rats, and that man contracts infection by oral or cutaneous contamination with the faeces of these animals. The author draws attention to the resemblance of *B. whitmori* to *B. pyocyaneus*, and suggests that it is intermediate between this organism and *B. mallei*.

# 

### 

109.

#### Epidemic Encephalitis.

T. P. SPRUNT (*Amer. Journ. Med. Sci.*, November, 1927, p. 660) discusses a series of 50 cases of epidemic encephalitis. There was no definite evidence of a constitutional predisposition to nervous disease, as in only seven cases was there a history of nervous talent in the family. The ages of the patients ranged from 12 to 69, the great majority falling within the third, fourth, and fifth decades. In the early stage the diagnosis was often difficult or impossible. The symptoms of onset were, in order of frequency, fever, diplopia, somnolence, insomnia, delirium, and ptosis. There was a great predominance of motor over sensory symptoms, as shown by the fact that 48 had some form of motor disturbance, as compared with only 15 with any evidence of sensory disturbance. Examination of the cerebro-spinal fluid was useful in excluding other disease of the nervous system. The pressure was normal in 18, increased in 6, and diminished in 5. There was a pleocytosis of ten cells or more per cubic millimetre in only 4 cases. The amount of globulin was more or less increased in 13, and in 10 out of 11 cases examined the sugar values were 70 mg. or more per 100 c.c.m. There were few marked disturbances of the autonomic nervous system. Mydriasis was noted in 19 and miosis in 10. The basal metabolic rate was not significantly changed, and the blood as a rule was normal. As regards prognosis, the probability of the development of Parkinsonism varies with the severity of the symptoms of onset; in the case of those with a severe onset 77 per cent. developed this syndrome, with a moderate onset 57 per cent., and with a mild onset only 28 per cent. Of 35 patients who were followed up 12 were able to work, 22 became chronic invalids, and one committed suicide. Treatment consisted in rest, freedom from too much responsibility, psychotherapy, dietetic and hygienic regimen, mechanotherapy and hydrotherapy, and sedative drugs, especially hyosclue hydrobromide in the Parkinsonian cases.

#### 110. Revaccination after Subcutaneous Injection.

W. KNOEFFELMACHER (*Wien. Klin. Woch.*, December 8th, 1927, p. 1541) records his observations on the revaccination of six children who had been vaccinated subcutaneously against small-pox from two to five years previously. Two children who had been given a 1 in 1,000 dilution of lymph two and three years previously showed typical vaccine lesions after cutaneous revaccination. Another three who had had the characteristic infiltration after subcutaneous injection of 1 c.c.m. of 1 in 100 dilution did not show any pustule formation on cutaneous revaccination four years later. The sixth child, who was given a subcutaneous injection of 1 c.c.m. of 1 in 200 dilution of vaccine lymph in 1919, also proved immune to cutaneous inoculation in 1924. The author concludes, therefore, that subcutaneous inoculation of diluted virulent vaccine lymph in dilutions of 1 in 100, 1 in 200, but not 1 in 1,000, confers immunity on children for some years.

111.

#### The Heart after Severe Diphtheria.

T. D. JONES and P. D. WHITE (*Amer. Heart Journ.*, December, 1927, p. 190) report the case of a woman, aged 22, who had had complete heart-block for nineteen years after diphtheria, and of a man, aged 22, who, three weeks after pharyngeal diphtheria, developed complete heart-block, followed by auricular fibrillation which persisted for at least six months. In view of the rather contradictory conclusions as regards the effect of diphtheria on the heart the authors investigated 100 patients who had had severe diphtheria at least five years previously; 70 were classified as "severe," and 30 as "moderately severe" diphtheria. All had been bacteriologically positive, and five to eight years had elapsed since the infection. The great majority of the severe cases had received 36,000 or more units of antitoxin. They had been diagnosed as having "myocarditis," some cardiac abnormality, or severe toxic diphtheria. In the subsequent investigation electro-cardiograms were taken in all cases, and skiagrams when the heart appeared to be enlarged. No patient gave an interval history suggestive of organic heart disease, nor were there any symptoms at the time of examination. No cardiac enlargement was found; only two patients showed ventricular premature beats, but 52 patients had slight to moderate sinus arrhythmia. No heart-block or other type of irregularity other than the above was detected, and no murmurs indicative of organic valvular disease were heard. The blood pressures were within the normal limits.

One electro-cardiogram showed a doubtful A-V nodal premature beat and ventricular escape. Two records showed slight (postural) right axis deviation. The authors conclude that there is no evidence that diphtheria has any appreciable and lasting effect on the heart.

112.

#### Parkinsonism Following Typhoid Fever.

C. G. NAGTEGAAL (*Nederl. Tijds. v. Geneesk.*, November 12th, 1927, p. 2079), who records an illustrative case, remarks that, with the exception of encephalitis, all forms of nervous sequelae have been described in typhoid fever, including meningitis and neuritis. On the other hand, most infectious diseases have been mentioned in the etiology of encephalitis, though typhoid fever has not. Nagtegaal now records the case of a girl, aged 15, who, directly after an attack of typhoid fever, the clinical diagnosis of which was confirmed by the Widal test, developed symptoms of Parkinsonism, including the mask-like facies, rigidity of the muscles, and change of character such as is met with after lethargic encephalitis.

113.

#### Mumps and Diabetes.

P. COURONNI (*Thèse de Paris*, 1927, No. 313), who records nine cases, four of which were fatal, in patients aged from 6 to 42, including those reported by Gillespy and Holden (*Journal*, 1917, ii, 115) and Patrick (*ibid.*, 1924, ii, 802), states that mumps is the only infectious disease besides syphilis which can give rise to a diabetic syndrome. Moreover, an attack of mumps in a diabetic subject may cause grave symptoms of acidosis. It is therefore indispensable, during the course of mumps and in convalescence from the disease, especially when there are signs of involvement of the pancreas, to make a careful examination of the urine, so as to employ an appropriate diet and insulin treatment at the very onset of the attack of diabetes.

114.

#### Intra-urethral Chancre.

B. BERNSTEIN (*Urol. and Uetan. Rev.*, November, 1927, p. 715) states that this term is applied to chancres whether occurring in whole or in part in the last half to three-quarters of an inch of the lumen of the urethra. The chancres may involve the whole orifice or only a portion of it; they are rarely met with below the fossa navicularis. They may be seen in full, in part, or be entirely hidden from external view. The features of an intra-urethral chancre are as follows: (1) a dirty white sloughing or necrotic centre bordered by the red ring seen in external chancres; (2) induration occurs early and is characteristic; (3) a sanious urethral discharge in which *Treponema pallidum* is found; (4) the urethroscope, when it can be passed—a matter of difficulty as a rule on account of the pain and obstruction—assists in the diagnosis; (5) inguinal lymphangitis and lymphadenitis. A pure treponemal infection is rare, and in all Bernstein's cases infection with the gonococcus was present also. The usual remedies are employed—namely, derivatives of arsenic, mercury, and bismuth. Healing of the chancre may be facilitated by injecting and washing the sore with a little of the salvarsan solution used for intravenous injection. Dilatation of the urethra should be started early to prevent stricture. Bernstein adds that many patients with tabes or general paralysis, who deny having had syphilis but admit gonorrhoea, have in all probability had an intra-urethral chancre.

### Surgery.

#### 115. The Radical Operation for Gastric and Duodenal Ulceration.

ACCORDING to M. FRIEDEMANN (*Zentralbl. f. Chir.*, November 26th, 1927, p. 3015) extensive gastro-duodenal resection for ulceration is less popular now owing to the pain, the diminished capacity of the stomach, and the larger percentage of post-operative complications than was anticipated. Friedemann finds that the number of definite recurrences is not excessive. Taking the statistics of various authorities who have kept their patients under observation for three years, the number of patients who were cured completely varies from 94 to 98 per cent. After short-circuiting, the number of successes was only 83.8 per cent. Another author reports that among over 300 patients who were submitted to the Billroth I operation there were only two

relapses, possibly due to old ulcers, undetected at the operation. In 70 cases of the Billroth II operation, only one doubtful jejunal peptic ulcer occurred subsequently. Another writer records one case of jejunal peptic ulcer among nearly 400 cases of Billroth II operation, although these patients were under observation for a shorter period. Friedemann received 374 replies from 450 patients, and found that 95.2 per cent. were either entirely or partially relieved, although 16.3 per cent. still complained of pain; 4.8 per cent. of the patients were unrelieved. Five patients had large or moderately large scar-herniae, and sixteen had small herniae. Friedemann concludes that after three to six years' observation of a large number of gastro-duodenal resections for ulceration the results are generally satisfactory and superior to those following any other operation. He dismisses the adverse criticisms as not justified by the results.

## 116.

## Fractures of the Sacrum.

A. SALOTTI (*Arch. Ital. di Chir.*, October, 1927, p. 633), who states that fractures of the sacrum were first described by Paul Barthele of Amsterdam in 1680, records two personal cases, and has collected twenty-three cases from the literature since 1826 in which there was an isolated fracture of the sacrum. His conclusions are as follows: Isolated fractures of the sacrum are most frequently horizontal, less frequently oblique as in the author's two cases, rarely vertical, and only exceptionally comminuted. Horizontal fractures are due either to direct trauma, such as the kick of a horse or a fall on the sacrum, or, more frequently, indirect trauma transmitted from the coccyx from below upwards. Oblique fractures may be due to the same causes as horizontal, and it is only the direction of the trauma transmitted from the coccyx that is to a certain extent oblique. Isolated vertical fractures are caused only by traction in the combined action of a fall on the feet or knees and the pull exercised by the trunk through the lumbar vertebrae, and are usually situated on one wing of the sacrum near the sacro-iliac joint. In some cases lateral trauma applied to the pelvis may give rise to subluxation of the lumbosacral joint, thus causing an increase of the lumbosacral angle, the diagnosis of which can be demonstrated radiologically.

## 117.

## Treatment of Mammary Carcinoma.

In mammary carcinoma, J. GUYOT (*Gynéc. et Obstét.*, November, 1927, p. 401) strongly advocates radiotherapy as a sequel to the surgical treatment of cancer of the breast. Following the Willy Mayer-Halsted method, he makes an extensive excision of the breast, apouerores, and axillary contents. Both pectoral muscles are removed, the removal of the pectoralis minor being particularly useful, as this discloses a subclavicular cellular space which contains the last axillary ganglion. The wound is closed with three silk sutures according to Mayo's technique. When the wound has cicatrized, x-ray treatment is started, doses of 3 to 5 Hönigknecht units per field under a filtration of 3 to 5 mm. of aluminium, a spark equivalent of 25 cm., and a skin anticathode distance of 25 cm. being repeated once a week for the first month, twice at fifteen days' interval during the second month, and then once a month for a year. At the end of this time further irradiation may be given every three months. Cases which do not benefit from this treatment, and in which recurrences and metastases are frequent, are those of advanced growths, and cancers in young and in syphilitic women. Guyot has obtained remarkable results by this method, many of his patients surviving for years (two for seventeen) after the operation. He adds that the irradiations must be non-penetrating and repeated at intervals; they will then cause no ill effects even if the treatment is continued for a long period. Pre-operative irradiation is said to be useless and to aggravate the conditions; post-operative high tension treatment should also be absolutely rejected.

## 118. Tumour of the Pancreas Cured by Operation.

P. MORNARD (*Bull. et Mém. Soc. Chir. de Paris*, November 4th, 1927, p. 661) records two cases showing identical conditions and diagnosed as tumours of the pancreas at the operation, but both of which were cured by a simple cholecyst-enterostomy. Twenty-two months had elapsed since operation in one case and thirteen months in the other. In these cases the symptoms prior to operation were typical of carcinoma, and during several months in which the patients were under observation they showed very marked cachexia. The usual course in cases of cancer of the pancreas is very rapid, and after laparotomy death follows in two or three months. In Mornard's cases the exact nature of the growth is unknown, since it was not possible to remove a portion for examination owing to the difficulty of dealing with haemorrhage. It is probable that the tumour was an adenoma or a fibro-adenoma. It is unlikely that it was a chronic pancreatitis, since this disease affects the whole gland, while in

these cases the morbid process was localized. It therefore appears justifiable, as these cases show, to perform cholecyst-enterostomy in cases of pancreatic tumour in the absence of enlarged glands and metastases when the nature of the growth is not known. Even if the growth should prove to be malignant the patient would be benefited and relieved of the jaundice.

## Therapeutics.

## 119.

## Synthalin Treatment of Diabetes.

N. PARISE (*Il Morgagni*, December 4th, 1927, p. 1921) records his observations on sixteen cases of diabetes in out-patient practice treated by synthalin; ten of them were mild and six of moderate severity. Two of the latter had previously been treated with insulin. The results of treatment were as follows. All the patients showed a considerable diminution of polyuria, but no outstanding changes were found in the chemical composition of the urine. Thirst was much reduced and in some patients entirely disappeared; hunger was also considerably modified by the synthalin treatment, and the general symptoms, including a sense of fatigue, underwent improvement. Symptoms of intolerance were not infrequently observed, especially at the commencement of treatment, in the form of loss of appetite, a feeling of oppression in the epigastrium, diarrhoea, and vomiting. Parise, like most writers, thinks that synthalin can be of benefit only in mild forms of diabetes, and only exceptionally in cases of moderate severity. It is contraindicated in severe cases because the large doses required cannot be tolerated. In moderate cases it can only be given when the patient can take sufficiently large doses. Parise has obtained good results by the alternate use of synthalin and insulin, the latter being substituted for a period of ten to fifteen days every thirty to forty days. Synthalin is chiefly indicated in mild cases, as it allows the patient to take a more liberal diet. Lastly, he regards it as specially suited for out-patient practice, because it does not require medical supervision, except at the start.

## 120.

## Parathyroid Extract in Infantile Tetany.

D. B. LEITCH (*Canadian Med. Assoc. Journ.*, November, 1927, p. 1321) discusses the use of para-thor-mono (a standardized parathyroid extract) in the treatment of infantile tetany as a means of raising the serum calcium content, which in such cases ranges from 5 to 8 mg. per 100 c.cm., as compared with 10 to 11 mg. per 100 c.cm. in normal blood. The potency of this preparation is indicated in units as 1/100 of the amount of extract which will produce an average increase of 5 mg. in the blood serum calcium of normal dogs of approximately 20 kg. weight over a period of fifteen hours. Notes of eight cases show that para-thor-mono, given subcutaneously at daily intervals, increases the serum calcium and acts beneficially in infantile tetany. As these were ambulant patients they were given 2 c.cm. or 40 units subcutaneously each day instead of the more rapid method of 5 units every two or four hours. Four injections as a rule sufficed to cause cessation of symptoms, although the serum calcium had not quite reached the normal by that time. In only one case was any other medication used, the para-thor-mono being given alone in order to demonstrate its value in increasing the serum calcium, though probably the improvement in symptoms and return of serum calcium to normal levels would have been further hastened if some form of calcium and cod-liver oil had been simultaneously administered from the beginning. In all the cases the diet was modified, the total quantity of milk being reduced, and more cereals, vegetables, and meat juices being added.

## 121.

## Indications for Digitalis.

C. C. WOLFERTH (*Amer. Journ. Med. Sci.*, December, 1927, p. 760) believes that success in the digitalis treatment of cardiac affections depends on the correct recognition of indications for its administration and on proper dosage; he discusses its uses in the treatment of abnormal rates and rhythms, and in heart failure with normal cardiac mechanism. In adults digitalis only slightly slows the normal heart, but in children and adolescents the effect may be much more marked. The drug usually fails to control simple tachycardia in adults with compensation, but in decompensated hearts it sometimes lessens the rapidity coincident on restored compensation. Digitalis can cause various forms of arrhythmia, may convert auricular flutter to fibrillation, and may even precipitate fibrillation in normal hearts. In sinus arrhythmia, ventricular escape, auriculo-ventricular rhythm, and sino-auricular block its use is contraindicated. Though not recommended it is not contraindicated in extra-systoles. The most useful field for digitalis therapy is in auricular fibrillation, due to a depressing rather than a stimulating action on the transmission of impulses through the junctional

tissues. Given according to Eggleston's principles rather than in small doses digitalis may be life-saving. The optimum ventricular rate at rest should be maintained, and if compensation has not been restored by this measure, or if it falls while the rate is maintained, the cardiac work should be lessened by rest in bed rather than by larger doses of digitalis. If treated vigorously with digitalis auricular flutter will be converted into fibrillation; if treatment be then abruptly stopped many cases will revert to normal rhythm. The drug is useless in paroxysmal flutter, and it should also be avoided in incomplete heart-block, but permanent complete block is not a contraindication to its employment. It is useful also in preventing the Adams-Stokes syndrome, in severe congestive heart failure, and in elderly patients with myocardial weakness. Digitalis is more valuable in mitral than in aortic lesions, though not contraindicated in the latter, nor in coronary disease. Its action on the blood pressure depends on the presence or absence of heart failure, and blood pressure levels are not important indications as to its use. Its administration is sometimes necessary in the cardiac failure of hyperthyroidism in order to support or stimulate the circulation, but its value in infectious such as pneumonia is still doubtful. The principles of digitalis therapy are the same in surgical as in medical cases.

## Dermatology.

### 122. Etiology and Treatment of Porokeratosis.

H. W. ACTON (*Indian Journ. Med. Res.*, October, 1927, p. 349) defines porokeratosis as a type of hyperkeratosis, which spreads in an irregular, centrifugal manner. This rare skin condition was first described in 1893 by Milcheli, who named it porokeratosis, since he considered that it occurred essentially round the sweat pores. During the past few years Acton has seen eight cases of this disease, and he gives short notes on each. The lesions are commonest on the hands, especially on the dorsal aspect, and may be present on the feet as well. They appear first as small, horny elevations resembling corns, which slowly enlarge, taking months or years to reach any conspicuous size, and may occur at any period of life. Etiologically the disease appears to be associated with some hereditary factor closely related to endocrine function. In two of the cases the basal metabolic rate was very low, indicating some deficiency in the action of the thyroid gland. Clinically the condition is characterized by the raised corn-like lesions; as they enlarge they form an irregular raised wall, which surrounds an atrophic depressed centre.

and hyperkeratosis. The endothelial cells and fibroblasts multiply in the corium, constrict the vessels by pressure, and atrophy sets in, causing the depressed, pigmented, wrinkled centre. The association of a familial tendency and the lowered basal metabolic rate suggests a partial correlation with hypofunction of the thyroid gland. The lesions can be cured in two or three weeks by thyroid medication. The dose of thyroid extract is regulated by the degree of deficiency of the metabolic rate. If this is diminished between 15 and 20 per cent, a dose of 2 grains of the dried glands is given twice a day, and if the diminution is more than 20 per cent, 3 grains twice a day. The dose is increased or diminished so as to keep the pulse rate between 90 and 100. Acton considers that porokeratosis is a localized keratosis with central atrophy (morphoea), and that it falls into the large group of so-called skin diseases—xeroderma, scleroderma, folliculitis, and morphoea—which are all partially associated with thyroid hypofunction.

### 123. Skin Affections in Asthma.

ACCORDING to K. H. BAAGÖE (*Acta Med. Scand.*, November 22nd, 1927, p. 189) the occurrence of cutaneous symptoms in asthma may have an etiological significance. The asthmatic attack has been attributed by some to an infection of the mucous membrane similar to that observed in the skin. In an examination of 124 asthmatics (92 children and 32 adults) the author noted skin diseases in 74 (57 children and 17 adults). Prurigo occurred in 36, strophulus or urticaria in 34, pruritis in 14, paraesthesia in 2, local oedema in 6, and other skin diseases (erythema of the face, herpes, hives) in 4 patients. In some cases only one skin affection was present; in others two occurred at the same time. Cutaneous tests with feathers, hair, foodstuffs, and pollen were performed on 70 of these patients, 57 giving positive reactions and 13 doubtful or negative ones. Baagöe asserts that in the patients in whom the skin disease broke out in connexion with the asthmatic attack there is no reasonable doubt as to the relationship between the cutaneous affection and the asthma. He emphasizes the facts that the skin lesions

occurred in paroxysms, were characterized by hypuraemia, oedema, and itching, and were frequently, if not always, due to idiosyncrasy. He agrees with the American authors that these skin diseases should be included in a common group under the name of allergic or idiosyncratic diseases of the skin.

### 124. Extensive Pigmentation of the Skin Associated with Amenorrhoea.

ACCORDING to A. F. SLATMANN (*Dermatol. Woch.*, December 10th, 1927, p. 1703) the female sexual organs, from puberty to the menopause, produce very definite metabolic and pathological changes in the skin, chiefly through the ovarian hormone; any derangement of this endocrine system may produce changes in the pigmentation of the skin. He describes the case of a girl, aged 19, with amenorrhoea and a skin eruption, both of a year's duration; the eruption had commenced on the limbs and spread over the entire trunk. She had had typhus fever at the age of 13. Menstruation commenced normally at 17, but a year later it became irregular and scanty, and it ceased entirely four months before admission to hospital. As the menstruation became irregular a red papular eruption appeared; the papules were as large as peas and caused no discomfort, but became more numerous and pigmented when menstruation ceased entirely. The nose, hands, feet, and legs were cyanosed and cold, but there was no other abnormality. Arsenic and other drugs, with local applications of Lassar's paste, autohaemotherapy, and terpene treatment, had no effect. On the limbs, especially on the extensor surfaces, there was a papular, coffee-brown eruption below the skin surface, which persisted on pressure. Between the papules the skin was normal. Histological examination of a papule showed piling up of the superficial epithelium, an atrophic stratum corneum, and many fresh haemorrhages into the stratum corneum. The papillary layer was relatively thinned; the capillaries were dilated and engorged, and there was much subepithelial small-celled infiltration. The sweat glands and roots of the hair were normal. An ovarian extract was administered, and in sixteen days definite improvement followed with free desquamation; the pigmented areas became smaller and paler. In three weeks normal menstruation was restored. There was no recurrence of the eruption, although, a year later, very pale isolated areas of pigmentation persisted, and the hands, feet, and legs were distinctly red and slightly cyanosed.

## Obstetrics and Gynaecology.

### 125. Prognosis in Abdominal Pregnancy.

JEANNENEY, BONNIN, FAYREAU, and BAUVALLÉ (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, November, 1927, p. 664) advocate speedy operation when the diagnosis of abdominal pregnancy is made before term. The maternal mortality after operation, according to Gneruer, is 6 per cent. in patients operated on at the fifth to seventh month, 22 per cent. at term, and 32 per cent. afterwards. The majority of the foetuses are malformed and non-viable, and, according to Baronnet, who summarized 300 cases, the foetal mortality is 83 per cent., while one-third of the surviving foetuses are malformed. The chance of securing a healthy infant is therefore so slight that it is unjustifiable to increase the maternal risk by deferring operation. J. LACOUTURE and L. MASSÉ (*ibid.*, p. 666) found that an infant born after abdominal pregnancy showed at the age of 2½ years normal mentality and no morbid physical characters except slight cranial and facial asymmetry. J. ANDERODIAS and DENIS (*ibid.*, p. 675) operated fifteen days before term for secondary abdominal pregnancy; a living, well formed infant was delivered, but died within a few days, and the mother died from embolus on the twenty-third day.

### 126. Placenta Praevia.

F. C. IRVING (*Surg., Gynecol. and Obstet.*, December, 1927, p. 834) discusses some of the problems of placenta praevia, based upon his own experience in 57 consecutive cases. There were no deaths from haemorrhage, but two mothers died from sepsis—a maternal mortality of 3.5 per cent.; the infantile mortality among viable infants was 45 per cent. The morbidity rate was 21 per cent. Delivery was effected mostly by dilatation of the cervix by a bag and Braxton Hicks version, and forcible dilatation of the cervix either manually or by traction on the foetus was never adopted. Two Caesarean sections were performed, one being followed by hysterectomy, and the placenta was generally removed by expression. Since sepsis is responsible for a considerable number of deaths Caesarean section, followed by hysterectomy, regardless of the state of the child, is indicated if there is a possibility that the patient has been infected, blood

transfusion being performed prior to operation. Irving summarizes the ideal treatment as: (1) an uninfected patient in poor condition from loss of blood should be given a preliminary blood transfusion, followed immediately, regardless of the infant, by a Braxton Hicks version as being the quickest way to stop the haemorrhage; (2) an uninfected patient in good condition, with the foetus dead, non-viable, or a monster, should have a Braxton Hicks version as affording the lowest maternal mortality; and (3) in an uninfected patient in good condition with a normal live child of sufficient size to warrant the assurance of survival Caesarean section affords the best means of saving the infant without unduly jeopardizing the life of the mother. In marginal placenta praevia simple rupture of the membranes is safe for the mother, but has no advantages over metemecrystis for the child.

#### 127. Acetone Treatment of Cancer of the Cervix.

G. GELBHORN (*Zentralbl. f. Gynak.*, December 3rd, 1927, p. 3114) views with satisfaction his twenty years' experience with acetone in treatment of cancer of the cervix uteri, and believes that this substance is in certain respects superior to radium in both inoperable and operable cases. The indications for acetone applications in inoperable cases are: (1) where radium is not procurable; (2) in patients whose general condition is so bad that absorption of the products of tissue degeneration due to radium application is likely to accelerate death—such cases account for the greater part of the 1 to 3 per cent. mortality associated with radium therapy in those cases; (3) where there is deep ulceration near the bowel or bladder, and radium would cause fistula formation; and (4) where the vaginal wall is the site of multiple or superficial nodules of neoplasm. With regard to operative preparation in operable cases, Gellhorn remarks that cauterization quickly arrests the bleeding, but is followed by a prolonged and copious watery discharge which weakens the patient. Radium applications before hysterectomy are said to be of doubtful value in the prevention of recurrences, and in the author's experience of operations performed from three days to three months later have been found to cause the pelvic cellular tissue to be congested and oedematous or densely cicatricial; in either case the operation is rendered difficult. Acetone stops the bleeding at once and causes the discharge to cease within a few days. Gellhorn's technique is as follows: One hour after an injection of scopolamine and morphine, without general anaesthesia as a rule, or after a few drops of ether have been given, projecting ulcerated parts of the tumour are removed with a large sharp spoon; subsequently, with the pelvis elevated, a well greased cylindrical speculum is placed in the vagina, and filled with one or two teaspoonfuls of pure acetone, which is allowed to remain for ten minutes. The pelvis is lowered and the vagina emptied, and mere acetone is now similarly applied for twenty minutes. This is repeated daily for one or two weeks, and then on every other day; after the first application morphine or an anaesthetic is unnecessary. Care must be taken that the vulva is not burnt by contact with the acetone. In certain cases acetone bisulphide is applied in powder form.

## Pathology.

#### 128. The Virus of Measles.

R. DEGWITZ (*Journ. Infect. Dis.*, October, 1927, p. 304) has found that the virus causing measles can be kept alive for several weeks outside the human body if the blood is taken from the patient just at the beginning of the eruption and diluted in the proportion of 1 in 7 to 1 in 10 with buffered salt solution containing the same number of anions and cations and showing the same pH as blood. The mixture must be kept at a temperature of 0° C. Measles produced by subcutaneous inoculation begins earlier than when it starts naturally or follows artificial inoculation of the respiratory mucous membrane; the symptoms are milder and of shorter duration. There seems thus to be an analogy between morbillization against measles and varioration against smallpox. Measles can be produced in human beings with the sterile blood of a measles patient or with dilutions of such blood which has passed through a Berkefeld filter. Sterile filtrates of nasal secretions collected in the pre-eruptive stage and diluted with normal saline are also capable of producing the disease. Measles virus can be grown in culture media containing plasma derived from susceptible or immune persons and diluted in a proportion of 1 in 6 or 1 in 7 with buffered normal saline. To keep the virus alive it must be associated with living cells such as the slowly growing bacteria regularly found in measles. Injection of sterile filtrates of cultures into human beings can produce reactions similar to measles, the specificity of which can be proved by the fact that such persons are later immune against large amounts of infectious blood. Monkeys (*Macacus rhesus*) can

be infected by injections of such material, and the specificity of the reactions can be proved by the fact that their serum collected after the reaction can protect infected human beings against measles, while the serum of normal measles has no such protective power.

#### 129. An Epidemic Due to Type IV Pneumococci.

G. H. ROBINSON (*Journ. Infect. Dis.*, December, 1927, p. 417) describes an epidemic of pneumonia during the first six months of 1927 in Pittsburgh, Pa., due apparently to Type IV pneumococci. The organisms were recovered from the sputum by the usual monso technique, tested for bile solubility and inulin fermentation, and used to prepare agglutinating serums in rabbits. Altogether 65 strains of Type IV pneumococci were studied; these fell into eight serological groups, though it is stated that not all strains were grouped. Twenty-eight of the strains fell into four groups, labelled A to D. These four groups were prevalent during the first three or four months of the epidemic; during the later stages members of the other groups appeared, possessing far greater heterogeneity. A study of the mortality of the different groups showed that 56 per cent. of patients infected with Group O died, whereas the mortality due to Groups A, B, and D varied from 14 to 33 per cent. The mortality in the whole epidemic was 37.3 per cent.; this was considerably higher than in the previous year, when the mortality due to Type IV strains was only 18.5 per cent.; the increase in death rate could be ascribed very largely to the high virulence of the Group O strains. It would appear, therefore, that in this epidemic a few dominant types of the usually heterogeneous Type IV pneumococci emerged, and that one of these assumed a much higher pathogenicity than usual. As the epidemic died away, the more homogeneous strains were replaced by more heterogeneous strains, similar to those encountered in non-epidemic times.

#### 130. Amato Bodies in Scarlet Fever.

J. A. TOOMEY and J. A. GAMMEL (*Amer. Journ. Dis. Child.*, November, 1927, p. 841) state that Amato in 1913 described small bodies—roundish, oval, elliptical, triangular, quadrangular, or crescent-shaped—in the cytoplasm of the ungranulated polymorphonuclear leucocytes of scarlet fever cases. As they were present from the first day of the invasion to the second and third day of desquamation he ascribed to them a differential value in the diagnosis of scarlet fever. The present authors, who regard the Amato bodies as nothing else than the inclusion bodies described by Döhle, examined 100 cases, consisting of 50 scarlet fever patients and 50 controls, and found that these bodies were not always present in scarlet fever, but occurred in other diseases, although they were present more frequently in scarlet fever than in any other acute infection.

#### 131. Composition of Human Milk.

B. MYERS (*Brit. Journ. Child. Dis.*, October–December, 1927, p. 249) reports on 184 separate analyses made of the milk of 84 nursing mothers, whose ages ranged from 16 to 30, the average age being 22. The results were as follows. The average analysis showed protein 1.53 per cent., fat 3.85 per cent., lactose 6 per cent., and the caloric value per ounce 18.95. The last third of the milk contained the highest percentage of fat. Although a large number of analyses showed fairly similar results, there was in many instances a distinct variation, especially as regards the fat content and the protein, which within certain moderately wide limits remained normal. The milk of a nursing mother was apt to vary to some extent even from day to day, but unless this variation was excessive it did not affect the infant. In conclusion, Myers maintains that for the purpose of an analysis or caloric value concentration the middle third or the whole of the milk in the breast should be used.

#### 132. Faecal Fat Analyses in Children.

G. A. HARRISON and W. P. H. SHELDON (*Arch. Dis. in Child.*, December, 1927, p. 338) recommend that the method of Holt, Courtney, and Fales should be used for the routine clinical examination of fat in the faeces of children. They state that normally not more than one-third of the dried faeces should be fat, and that of that fat not more than one-third should be unsplit, it being borne in mind that in infants as much as one-half of the dried faeces may consist of fat. They add that faecal fat percentages give a rough indication of the efficiency of the digestion and absorption of fat, though, by themselves, such estimations are seldom, if ever, pathognomonic of any one disease. The total fat gives a measure of the efficiency of absorption, while the ratio of unsplit to split fat indicates the efficiency of fat digestion. Separate estimations of free fatty acids and soaps are said to afford little or no useful clinical information. The ratio of free to combined fatty acids depends largely on the reaction of the intestinal contents.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 133. Auricular Fibrillation in an Apparently Normal Heart.

W. D. REID (*Boston Med. and Surg. Journ.*, December 29th, 1927, p. 1213) describes a case of auricular fibrillation in an apparently normal heart to show the importance of recognizing this condition, since normal rhythm and perfect health may be restored by appropriate treatment. Irregularity had first been noticed by the patient four years previously, following over-exertion on one occasion; no further symptoms were noticed until eleven months later, when, after an attack of influenza, the patient became unable to work for more than two hours a day on account of dyspnoea and palpitation. There was nothing in the history to suggest rheumatic infection, and with the exception of a completely irregular rhythm at a rate of about 100 no abnormality was discovered on clinical examination. A diagnosis of auricular fibrillation was confirmed by the electro-cardiogram. Two doses of digitalis leaf (6 grains each) were given, and on the next day the patient discovered that he had less breathlessness on exertion than at any time since the onset of his illness. Two days later quinidine sulphate was administered (36 grains spaced over eight hours), and four hours afterwards the rhythm was observed to be normal, this being demonstrated by the electro-cardiogram. X-ray examination before and after treatment showed that some dilatation of the right side of the heart, which had been present during the illness, had disappeared on the restoration of normal rhythm. The author emphasizes the futility of inadequate digitalis therapy. During the illness tincture of digitalis, half a drachm daily, had been given without benefit, but it was found that considerable increase in the dose for one day produced marked amelioration of symptoms. Since the case was considered to be suitable for treatment with quinidine sulphate it was decided to make, if necessary, vigorous use of this drug in the attempt to restore normal rhythm, continuing its administration either until regularity was established or toxic symptoms made their appearance. As it happened, the effort was successful before this limit was reached. No recurrence of irregularity has been noticed during the ten months following its disappearance.

### 134. The Heart in Typhus.

D. DANIELOPOLU, N. LUPU, C. NICOLAU, and PETRESCO (*Presse Méd.*, October 15th, 1927, p. 1257) state that typhus fever is one of the infections in which the heart is most frequently affected. The lesions are localized exclusively in the myocardium. The cardiac phenomena which occur in the course of the disease, usually during the second week, are more intense in the hypertoxic than in the mild forms, and in old persons than in the young. In the hypertoxic forms they become progressively worse and continue until death, even after the temperature has reached normal. The cardiac symptoms, therefore, follow the same course as the other symptoms of typhus. In the hypertoxic forms the low arterial tension, morphological changes in the blood and cerebro-spinal fluid, and the nervous symptoms disappear in the mild forms as soon as defervescence occurs, but become progressively more pronounced until death in apyrexia in the hypertoxic forms. Myocardial insufficiency in typhus is usually manifested by a pulse rate of over 120, sometimes exceeding 140 to 150, and occasionally accompanied by extrasystoles. As in all acute infections it is favourably affected by strophanthin in fractional doses. On histological examination the myocardium shows inflammatory and degenerative lesions. The stellate ganglion presents an intense diffuse or nodular infiltration of lymphocytes, polymorphonuclear and plasma cells, with often intense degenerative lesions in the nerve cells. Similar lesions are found in the vagus nucleus.

### 135. Modification of the Schick Test.

W. H. PARK (*The Nation's Health*, November, 1927, p. 50) states that he found in 1922 that if toxin-antitoxin of the standard degree of incomplete neutralization was given immediately under the skin it acted both as an immunizing agent and as a method of determining immunity. At the present time, he says, all the first injections of toxin-antitoxin by the New York City Health Department medical inspectors are given in this way, i.e. being injected directly under the skin at the interior lower part of the arm just above the end of the elbow. On the sixth or seventh day the arms are inspected and those patients who show no skin reaction

are given no further injections. Those with a very slight reaction are given a second injection, and those who have definite reactions receive two more injections. The time and labour of the extra Schick injection are thus saved and only the susceptible children receive the three injections. In children under six years old the reactions are practically the same as with the Schick test. In older children the reactions are somewhat increased owing to a few persisting pseudo-reactions. This immunizing injection has now been used as a modified Schick test in more than 100,000 children. Park thinks that the use of the Schick test after injections of toxin-antitoxin, though of great value to individual children, is not necessary as a general public health procedure.

### 136. Tularaemic Peritonitis.

S. C. FULMER and M. J. KILBURY (*Journ. Amer. Med. Assoc.*, November 12th, 1927, p. 1661), who report an illustrative case, state that there have been no previous examples on record of abdominal complications in tularaemia. Their case, which occurred in a man aged 40, was apparently an ordinary attack of tularaemia until abdominal symptoms developed three months after the initial infection. The abdominal condition resembled a low-grade peritonitis with ascites and gaseous distension. About 20 c.cm. of greenish-tinged, cloudy ascitic fluid was withdrawn. Cultures on ordinary media and smears from the ascitic fluid failed to show the presence of organisms. The fluid was then centrifuged, the sediment was mixed with 5 c.cm. of normal saline, and injected into a guinea-pig, which died of tularaemia in four days. The organism was isolated from the spleen and grown on glucose cystine meat infusion agar of pH 7.3, as recommended by Francis, who first described tularaemia.

### 137. Oesophagectasia in a Child.

J. A. M. CAMERON (*Arch. Dis. in Child.*, December, 1927, p. 353) reports the case of a male child who suffered from dilatation of the oesophagus due to cardiospasm, and died when 6 years old. He discusses the pathological findings in a series of eight cases of recurrent attacks of vomiting, chronic in nature; in all an infiltration in the intermuscular layer was found which had invaded Auerbach's plexus in the lower end of the oesophagus. The present case afforded evidence of bacterial invasion and supports the theory of a toxic basis of the condition. The ganglionic changes result in the stimulus of food being followed by contraction only; the retention of the food causes the stomach to dilate, and the circular muscle hypertrophies.

## Surgery.

### 138. Abscess of the Spleen in Typhoid Fever.

L. MONTEL (*Ann. de Méd.*, November, 1927, p. 489), who reports a case of abscess of the spleen in typhoid fever, alludes to the one reported by Morel, Dambrin, and Tapie (*Epitome*, April 24th, 1926, para. 447), and remarks that the abscess is usually single and situated at the upper pole of the organ, as in thirteen of the fourteen cases where the localization was noted. Occasionally multiple abscesses have been observed, ranging in number from two to eight. The pus is greyish or yellowish in colour and often haemorrhagic. The organism most frequently present is the typhoid bacillus. The symptoms are unobtrusive, being usually disguised by the other manifestations of typhoid fever; pain is the most constant one. No definite information is provided by palpation, percussion generally shows a definite splenomegaly, and the fever varies in character. The general condition is grave and the face is pinched. In view of these vague signs Montel thinks it is not surprising that the condition is as a rule not discovered until the necropsy. If left to itself, splenic abscess either causes death at once or gives rise to a series of complications in the abdomen, such as peritonitis and perforation of the colon; or more often in the thorax, such as adhesive, serous, haemorrhagic, or purulent pleurisy. Montel's case, which occurred in a man who had been twice inoculated against typhoid with a heated polyvalent vaccine, five months and seventeen months previously, was remarkable in that abscess of the spleen was complicated by purulent pleurisy on the left side and perforation of the diaphragm. The organism isolated from the blood was probably of a typho-paratyphoid nature, but distinctly atypical. The Widal reaction did not give any definite result with *B. typhosus* or *B. paratyphosus* A or B.

## 139. Isolated Polyposis of the Small Intestine.

R. GEHRIG (*Deut. Zeit. f. Chir.*, December, 1927, p. 286), who records an illustrative case, remarks that in comparison with polyposis formation in the large intestine polyposis in the small intestine, especially the duodenum, is rare. Many observers have drawn attention to the hereditary factor in intestinal polyposis, but opinion differs considerably as to the importance of age. While Staemmler regards intestinal polyposis mainly as a disease of advanced life Doering states that it is chiefly found in youth and middle age. The condition is essentially chronic. Attacks of intestinal obstruction which recur frequently for years and subside spontaneously should suggest intestinal polyposis. Treatment, which was formerly limited merely to extirpation of the polypi, should consist of resection of the affected intestinal segment. Gehrig's patient was a girl, whose mother had died at the age of 34 from ileo-caecal intussusception, probably connected with polyposis, but no autopsy was performed. The daughter had her first attack of intestinal obstruction at the age of 7. Operation revealed intussusception of the small intestine associated with four polypi, which were excised. The patient subsequently had attacks of colicky pain almost every year in the autumn, when the diagnosis of duodenal ulcer was often made. At the age of 18, when she had an unusually violent attack, laparotomy was performed, when an enteric intussusception was found associated with numerous large and small polypi of the duodenum and upper part of the small intestine. Resection of the affected part was performed, but death followed fourteen hours after the operation. At the necropsy the lower part of the small intestine and the whole of the large intestine were found to be normal.

## 140. Incidence of Hernia in Children.

D. PATERSON and G. M. GRAY (*Arch. Dis. in Child.*, December, 1927, p. 328) investigated 1,018 cases of hernia in children and noted that among patients attending the out-patient department of a children's hospital the incidence of hernia was less than 1 per cent. The sex incidence of hernia in children was found to be four males to each female. The authors report that inguinal hernia is about four times as common as umbilical hernia, and that the sex incidence in this variety was nine males to each female. Spontaneous cures of hernia have been claimed by some writers, though others hold that such do not exist. Paterson and Gray state that there was an apparently spontaneous cure of inguinal hernia in one-fourth of all their cases, the tendency being higher in females than in males. A right inguinal hernia was present in 62 per cent. of their cases, a left in 20 per cent. only, and a double hernia in 18 per cent. In umbilical hernia the sex incidence was equal, and in half the patients under the age of 12 an apparently spontaneous cure occurred. The routine treatment of inguinal hernia at the hospital where these observations were made is to postpone the operation until after the first year, except in special circumstances. The authors mention that there is a wide discrepancy in the statistics on a number of the above-mentioned details, and quote those of various English and American authorities to illustrate this point.

## 141. The Thymus Gland in Graves's Disease.

As a result of his own observations and those of other workers H. HABERER (*Wien. Klin. Woch.*, December 1st, 1927, p. 1501) concludes that the thymus, like the thyroid gland, plays an important part in the endocrine dysfunction associated with Graves's disease, especially in the more severe cases. A large thymus has been found in nearly 100 per cent. of patients dying of heart failure after thyroidectomy operations, while this was present in only 82 per cent. of those who succumbed to the disease without operation, and in 44 per cent. of those dying of intercurrent affections. When performing thyroidectomy for this disease he has, therefore, in a series of 61 cases, of which 45 were classified as severe or very severe, removed as much as possible of the thymus as well, generally at the same time. Occasionally, though only a small thymus was found, microscopic examination showed delayed involution of the glandular tissue. The results in the majority of the cases were very satisfactory; many of the patients were operated on more than seven years ago and some more than fourteen, and, in spite of considerable emotional stress and worry, in some instances there was no recurrence of symptoms, though in a few the thyroid gland enlarged again subsequently. In three out of the four deaths which occurred in the series there was marked post-operative restlessness and tachycardia, and large residual portions of the thymus were found at necropsy. Haberer thinks that failure in these cases was probably due to the technical difficulties of removing sufficient of the thymus. The fourth fatal case was that of a patient five months pregnant with advanced Graves's disease, aortic stenosis, and hypertrophy of the right ventricle and dilatation of the left. He concludes that

for the successful surgical treatment of a large proportion of cases of Graves's disease reduction of the activity of the thymus is necessary; until this can be accomplished medically, operative removal of as large a portion of this gland as possible is advisable.

## Therapeutics.

## 142. The Treatment of Hodgkin's Disease.

L. LORTAT-JACOB and P. SCHMITE (*Paris Méd.*, December 3rd, 1927, p. 452) draw attention to the honours produced by the combined use of x-ray and biological therapy in Hodgkin's disease, and report a case in which this method proved most efficacious. Carefully filtered rays were used two or three times a week, and always caused great amelioration of the symptoms; the ganglionic masses disappeared, functional signs lessened, the pruritus became less troublesome, and the general state improved. At the same time the leucocytes diminished in number and the erythrocytes rapidly increased. The authors agree that this improvement is only transitory, and sooner or later the symptoms recur with a fatal termination. In biological treatment, Lindstroem, having obtained only inconstant results with injections of human rabbit's and sheep's serum, the authors advocate the use of homologous serum. In the present case the serum employed was obtained from another patient suffering from Hodgkin's disease who had been treated with x-rays. This was given in two courses, 93 c.c.m. being injected subcutaneously in ten days during the first, and 11 c.c.m. in the same time during the second course. The first injection caused a slight febrile reaction, but no general disturbances. During this stage of the treatment the red cells increased from 2,800,000 to 4,300,000 per c.mm. and the white cells decreased from 22,800 to 7,800. Following these injections x-rays were administered, and in twenty-eight days the patient was apparently cured. The result of the blood examination showed that the serum treatment was an undoubted factor in the apparent cure; its action may be due to protein shock, a veritable vaccination reaction, or to the liberation in the blood of leucolytic products of disintegration. The authors are inclined to favour the last theory, since many experimenters have shown that the serum of irradiated leukaemic patients causes *in vitro* a partial leucolysis in normal or other leukaemic blood. Deep radiotherapy and radium have given no better results than superficial irradiation.

## 143. Treatment of Typhoid Fever by Anti-gangrene Serum.

M. WEINBERG and G. THIBAUT (*C. R. Soc. de Biologie*, December 2nd, 1927, p. 1476) record a severe case of typhoid fever treated successfully with a serum prepared against the causative organisms of gas gangrene. During the first three weeks of illness antityphoid and anti-coli vaccine by the mouth, Redet's antityphoid serum, and, later, the antityphoid bacteriophage, were all tried, but without avail. The patient had a severe intestinal haemorrhage, and his red cells sank to 2,900,000 per c.c.m. As his stools were very fetid and showed microscopically a mixture of typhoid bacilli and *B. perfringens*, it was decided to administer anti-gangrene serum. Grassot and Gory's antityphoid serum was given subcutaneously and a mixture of anti-*perfringens* and polyvalent anti-gangrene serum by the rectum. The patient's condition rapidly improved; a second injection was given therefore on the next day, and an injection of antityphoid serum alone on the third day. After the second injection the temperature commenced to fall, and the stools became inodorous; the red cells rapidly rose to 4,200,000. The patient apparently recovered quickly. The authors conclude that the anti-gangrene serum was largely responsible for this result, and recommend its administration in all severe cases of typhoid fever.

## 144. Liver Feeding in Pernicious Anaemia.

From the results obtained in fourteen cases of pernicious anaemia C. A. ELLIOTT (*Med. Journ. of Australia*, November 12th, 1927, p. 672) concludes that the addition of sufficient liver daily to an adequate well balanced diet will produce a prompt remission in most cases of pernicious anaemia, the response by the reticulocytes apparently being characteristic of this disease. He finds that the liver may be cooked or raw, while some patients prefer to take it well ground and diluted with orange juice. In some cases administration by means of a stomach tube is advisable, and hydrochloric acid may be given also. Under the liver diet, the red blood cell count and haemoglobin increased, the colour index fell below one, and the megalocytes and irregular forms diminished. General improvement occurred, the bilirubinaemia became normal, and the glossitis and gastro-intestinal symptoms

quickly cleared up. Gastric anacidity, however, and symptoms referable to the spinal cord persisted, although numbness and tingling decreased or disappeared. Of the fourteen patients, eleven had complete remissions of their anaemia and a corresponding general clinical improvement. One of the remaining three received the liver for only one month, and the two others, elderly and extremely debilitated, who were given raw liver purée by the stomach tube, developed suppurative broncho-pneumonia and died, this being possibly attributable to the method of administration. In other types of severe anaemia there was no such marked response to liver feeding as was seen in the pernicious form.

## Laryngology and Otology.

### 135. Misleading Symptoms of Laryngeal Obstruction.

G. PANSINI (*Rev. de Laryngol., d'Otol. et de Rhinol.*, October 31st, p. 611) describes two cases where the unsuspected inhalation of a foreign body gave rise to symptoms of croup and for which antidiphtherial serum was given. The first patient was a child aged 6 months, who was brought to hospital with signs of laryngeal obstruction. It had had dyspnoea, cough, and loss of voice for three days with some fever, and antidiphtherial serum had been administered without improvement. Respiration continued difficult, with intermittent periods of normal breathing. The pharynx and larynx were reddened and swollen, without any exudate. After two days in hospital the child had a violent attack of coughing and expelled a melon seed, with a considerable amount of mucous secretion. It was then ascertained that the child had had a fall while eating a slice of melon and had cried loudly for a few moments; the symptoms had not appeared for several hours afterwards. In the second case a similar series of symptoms was related. This child was 10 months old, and had signs of laryngeal obstruction, with cough and loss of voice, but there were no intermittent periods of normal breathing. Tracheotomy was performed and the vertebra of a fish was found in the subglottic space. The child had been present at a meal several hours before the symptoms appeared, and must have secreted and swallowed a morsel of fish then. These cases demonstrate how in a small child a foreign body may be present in the most unsuspected cases, and may give rise to symptoms which do not suggest a foreign body, but rather an acute infection or spasm; the foreign body may have been inhaled some considerable time before any symptoms are noticed.

### 136. Malignant Tumours of the Nasal Sinuses.

H. A. BARNES (*Arch. of Otolaryngol.*, August, 1927, p. 123) reports a series of twenty-five cases of malignant disease of the accessory sinuses of the nose. He considers that the majority of the cases begin in either the maxillary antrum or the ethmoid cells. In those cases where the first symptom is pain about the molar teeth, the site of origin is usually in the antrum; when the earlier symptoms are nasal haemorrhage and obstruction the growth probably began in the ethmoidal labyrinth. The sphenoidal sinus rarely appears to be the primary site, although affected by extensions. The frontal sinus is rarely involved by growth, though usually badly infected and full of granulation tissue. The majority of the cases are carcinomata, usually epithelial in type. The author's method of treatment consists in a very free removal of the tumour, with a margin of healthy tissue. His incision starts at the outer angle of the eyebrow, follows the brow and the naso-maxillary suture, and then makes a wide sweep under the eye, finishing up just below the outer angle of the orbit. This gives a very wide approach to the area of the growth. A Moore's lateral rhinotomy is then practised, with extensions until all the malignant tissue is removed. The soft tissues of the cheek are removed so as to leave the cavity wide open for inspection and treatment. At the end of the operation the cavity is plugged with gauze with which are incorporated tubes of radium of from 100 to 200 mg. strength, which are left in from twenty-four to forty-eight hours. The patients are examined carefully once a week and any suspicious area of granulation tissue at once treated with radium. This is very easily done by means of the open cavity in the cheek, and such inspection is continued, at gradually increasing intervals, for several years.

### 137. Ocular Signs of Labyrinthine Disease.

L. BALDENWECK (*Arch. Internat. de Laryngol.*, September-October, 1927, p. 897) has carefully investigated the ocular reaction of diseases of the labyrinth. Spontaneous vestibular nystagmus has certain definite characteristics, and, especially when unilateral, is readily distinguished from central. Horizontal nystagmus to the healthy side indicates complete

loss of function of the labyrinth. Past-pointing and falling are always to the same side as the slow component of the nystagmus. If this rule is not followed an extra-labyrinthine lesion, usually a cerebellar abscess or tumour, is indicated. Nystagmus due to movement of the head varies as to whether the movement is rapid or slow. In the former the semi-circular canal system and in the latter the otolith apparatus is brought into action. Hyper-excitability of the labyrinth does not indicate a pathological process, but is part of a general nervous irritability; hypo-excitability in itself is insufficient to indicate the site of the lesion. Caloric tests have the advantage that only one side is examined at a time. The technique of Bárány is said to be rather more reliable than the minimal stimulation of Kobrak. In the caloric tests the latency of the nystagmus indicates the state of the labyrinth, the duration indicates the condition of the central mechanism. The electrical reaction is not very conclusive, but if it gives results different from the normal a central lesion is to be suspected. If other tests show the central region to be normal the lesion must be in the vestibular nerve.

### 138. Tuberculosis of the Middle Ear.

F. R. SPENCER (*Arch. of Otolaryngol.*, September, 1927, p. 242) thinks that tuberculosis of the middle ear in adults is more common than is generally supposed, though it is difficult to isolate the bacillus from the discharge. In the child it is a very serious disease and extends to all parts of the temporal bone; it is acute, and causes widespread necrosis. In adults the disease is more chronic and tends to be restricted to the middle ear. In tuberculous otitis there is frequent caries of the ossicles, and paralysis of the facial nerve is a common complication, especially in children. As in the lungs, the blood vessels are eroded and haemorrhages occur, but they are very small and are often unnoticed. The auditory meatus contains mucus and pus, and there are usually multiple perforations of the tympanic membrane which tend to coalesce in time until almost the whole membrane has disappeared and the middle ear becomes filled with pale, flabby granulations. Mastoiditis is frequent in children, but rare in adults, though in some chronic cases an attack of influenza may light up the whole condition. Intracranial complications consist mainly of meningitis, which is rapidly fatal. In chronic adult cases the prognosis is good, but in children the course of the disease is likely to end in meningitis. Heliotherapy is the best conservative form of treatment, but operation is necessary in cases of necrosis.

## Obstetrics and Gynaecology.

### 139. Climacteric Disturbances.

H. CURSCHMANN (*Med. Klinik*, November 18th, 1927, p. 1759) believes that the differential diagnosis of climacteric pathology is an important subject for study. He finds that the symptoms vary greatly according to the racial type and the psycho-physical constitution. The "pyknic" (thick-set, muscular) woman is said to suffer much less at the menopause than the patient of the "asthenic-plectic" type. The intelligent, sensible, busy woman seldom becomes the depressed, unhappy neurasthenic at the menopause. Curschmann doubts the wisdom of regarding these climacteric disturbances as largely functional and relatively unimportant. While menopausal hot flashes, morbid blushing, and dermatographia are common, yet migraine, acroasphyxia, and anaphylactic asthma diminish or disappear. Obesity very commonly follows the menopause; less frequently the patient becomes thin. Rarer forms of endocrine disturbance are "late" osteomalacia, psychoses of the depressive, melancholic, or manic-depressive type, changes of character, sexual excitement, unreasoning jealousy, hysteria, and neurasthenia. Again, hyperaemia and swelling of the thyroid, thymus, and adrenal cortex, analogous to those conditions occurring in pregnancy, are common. All these symptoms indicate profound disturbances of the hormone and endocrine balance. The author thinks that the absence of the ovarian hormone alone will not account for this, and he advises that the patient's general health should be investigated thoroughly, rather from the physician's than from the gynaecologist's standpoint. For instance, emaciation, debility, and pruritus are sometimes attributed to the climacteric, when an examination of the urine shows that the patient has diabetes. He adds that there may be commencing or definite arteriosclerotic changes in the heart, kidneys, brain, and abdominal viscera, or carcinoma may appear; careful diagnosis is required to exclude these and to determine the right lines of treatment, which include organotherapy, spa and electric treatment, psychotherapy, and the administration of sedatives.

**150. Diagnosis of Sterility in Women.**

DISCUSSING the diagnosis and treatment of uterine and tubal sterility, G. COTTE and F. J. MARTIN (*Gynéc. et Obstét.*, October, 1927, p. 299) state that when Ipiodol is introduced into the uterus and the Fallopian tubes are patent the fluid escapes into the peritoneal cavity, where, in normal cases, it disappears without there being any evidence of injury. When, however, the tube is occluded or otherwise unhealthy, the Ipiodol cannot be evacuated, but is taken up by macrophages, or an interstitial rupture of the tube may occur. The authors have never seen any serious consequences following injection of Ipiodol when the apparatus is fitted with a pressure gauge. E. EXCHAQUET (*ibid.*, p. 305) recommends insufflation at low manometric pressure (22 cm.). He has employed this method fourteen times in 10 cases of sterility without any ill effects. In cervical stenosis, with or without endocervicitis, he recommends diathermy in preference to Pozzi's operation. He agrees that endocervicitis is an important cause of sterility, and that either of these operations secures free drainage, often curing the endocervicitis and obviating subsequent treatment. R. PROUST and C. BÉCLÈRE (*ibid.*, p. 317) claim that radiological examination after the injection of Ipiodol gives more valuable information regarding the condition of the uterus and Fallopian tubes than simple insufflation. They do not think that intrauterine injection of Ipiodol prevents subsequent pregnancy, and cite four cases reported by Hensler in which tubal permeability was restored after repeated injections of Ipiodol, and two patients subsequently became pregnant. For those reasons Proust and Béclère hold that Ipiodol injections are not only harmless, but may have a definite therapeutic action, and are therefore the best procedure in the diagnosis of sterility. BEÜTZNER (*ibid.*, p. 327) confirms Douay's enumeration of the dangers of insufflation—namely, rupture, infection, embolism, and syncope. He reports a case in which the patient, shortly after insufflation with Douay's apparatus, had a tubal pregnancy.

**151.****Symphysiotomy.**

J. ORTIZ-PEREZ (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, November, 1927, p. 623) describes the experience of a Cuban obstetrical clinic with regard to labour in moderately contracted pelvis, with a conjugate of not less than 8 cm. He states that 60 per cent. of patients with such contraction are delivered spontaneously, and that during five years approximately fifty-four symphysiotomies to each Caesarean section have been performed. The routine practice is to allow labour to proceed and to employ symphysiotomy when it has been proved that normal delivery is impossible. The series included only two foetal deaths, and the last forty-one cases were without foetal mortality; there was no maternal death. In cases in which the foetus is already dead not only is symphysiotomy less dangerous than Caesarean section, but, on account of the pelvic enlargement which is produced, the mother is left in a more favourable position for subsequent confinements. At the same time as the symphysis is divided from above downwards by a tenotome, separation of the pubes by two or three fingerbreadths is effected slowly. Careful observation of the uterine tonicity is necessary, and valuable assistance is derived from the administration of morphine in some cases, and in others of pituitary extract. Application of forceps is occasionally required. It is admitted that in cases of symphysiotomy perineal tears are frequent, especially in the first and second labours, and that extensive episiotomies are not infrequently necessary.

**152.****The Endocrine Glands in Gynaecology.**

ACCORDING to SERDJUKOFF (*La Gynéc.*, September, 1927, p. 513) a certain amount of physiological enlargement of the thyroid glands commonly occurs at puberty, and periodical changes in its size are often associated with menstruation. Graves's disease also frequently manifests itself at or soon after puberty, when it is due to pronounced modification of the functions of this gland. Either deficiency of the menses or excess may be produced by hyperthyroidism. At puberty the parathyroid and the suprarenal glands also become more active, while the development of the mammary glands is also closely correlated with that of the ovaries. The influence of gestation and lactation on the endocrine glands is established both clinically and experimentally. During pregnancy there is a progressively increasing hyperactivity of the thyroid, and it has been suggested that eclampsia and the chorea of pregnancy may be due to, or associated with, parathyroid disorders. During this time also the anterior pituitary lobe undergoes hyperplasia, and may be indicated by a change in the facial aspect of the patient. No morphological changes can be found in the posterior pituitary lobe, notwithstanding the marked action of its secretion on the parturient uterus. Serdjukoff concludes that hormones produced by the foetus

and the placenta stimulate the development of the mammary glands, though there is as yet no satisfactory explanation of the onset of lactation after delivery. Since the work of the liver in the detoxication of poisonous substances is greatly increased during pregnancy, hepatic disorders are likely to occur. At and after the menopause there is atrophy of the endocrine glands and of the uterus, ovaries, and glandular tissue of the mammary glands; the whole endocrine system becomes reorganized, and ill balanced action often results, leading to such manifestations as goitre, myxoedema, Graves's disease, acromegaly, and obesity.

**Pathology.****153. Interstitial Neuritis Caused by the Virus of Rabies.**

ACCORDING to S. NICOLAU and I. A. GALLOWAY (*C. R. Soc. de Biologie*, January 13th, 1928, p. 31) the virus of rabies is able to spread along the nerves in both a centripetal and a centrifugal direction. Roux demonstrated the presence of the virus in the nerves of the healthy arm of a man who had been bitten on the opposite arm. Roux and Nocard brought evidence to show that after intracerebral infection of dogs the virus reached the saliva by passing down the nerves. The present authors have performed a series of experiments to determine whether the virus is demonstrable in the peripheral nerves of rabbits after intracerebral injection with the rabies virus. A street virus was used, producing death in ten to thirteen days after inoculation, and giving rise to very obvious Negri bodies, which rendered diagnosis very simple. The brachial or sciatic nerves of rabbits inoculated intracerebrally were themselves inoculated into the brains of fresh animals. Altogether these nerves were injected fifteen times into the brain of twelve rabbits, and each time the inoculated animal developed rabies. Histological examination of the peripheral nerves of animals inoculated by the corobral route showed a mild degree of interstitial neuritis. The sheaths of the nerves were intact, but in between them was an infiltration with mononuclear cells. Perivascular cuffing was observable, the chief cells being lymphocytes, plasma cells, and large mononuclears. No degenerative lesions were found in the nerves. The authors conclude that the street virus of rabies, when introduced into the brain, is able to travel centrifugally and to reach the peripheral nerves, in which it sets up a mild degree of interstitial neuritis.

**154.****Mode of Action of Ingested Urea.**

L. ROHÁČEK (*Bratislavské Lekárske Listy*, December, 1927, p. 598) states that although urea is no more considered a toxic substance, it may still in certain circumstances bring about a condition which, by its symptoms, resembles nephritic uraemia. Thus symptoms of intoxication were observed after the ingestion of small quantities of urea in two patients with oedema and cardio-hepatic oliguria. He adds that the variation of the diuretic action of urea is most remarkable. In an advanced case of cirrhosis of the liver, urea therapy not only prevented the renewal of the ascites, but arrested the further advance of the disease. Many other successes in cirrhotic conditions are reported, but failures have been met with just as frequently. After the ingestion of urea (in the successful cases) there results not only an increased elimination of urea, but also of water. In refractory cases the concentration of urea in the urine becomes unusually high, this disturbance being caused not by disease of the renal epithelium, but by failure of the ingested urea to release the water assembled in the tissues. The diuretic qualities of urea depend upon the liver function in two ways. (1) The production of urea has its chief site in the liver. An inadequate production may cause disturbances in the elimination of water and salt, and in the same way lead to the appearance of oedema and ascites. (2) The liver influences the water and salt metabolism, possibly through the hormones or diastases, and preserves the balance between the concentration of sodium chloride in the blood and in the urine.

**155. Bony and Cartilaginous Deposits in the Tonsils.**

C. HIRSCH and M. H. CORTEN (*Zeit. f. Hals-Nasen- und Ohrenheilk.*, December 22nd, 1927, p. 397) record the case of a diphtheria carrier, a woman aged 22, on whom tonsillectomy was performed without any difficulty, with the result that no more diphtheria bacilli were found in the swabs. On examination of the capsule of the excised tonsils islands of cartilage and bone were discovered, a rare condition of which only about thirty cases have been recorded, the first having been reported by Orth in 1893. There did not appear to be any connexion between the carrier state and the cartilaginous and bony deposits.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

156.

### Unrecognized Mycoses.

ACCORDING TO G. DURANTE (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, November 17th, 1927, p. 1513), mycoses in the tissues of man are exceptional, apart from well marked infections such as actinomycosis, oidium, and aspergillus. He records the case of a woman who died from eclampsia. Near the vessels in the stroma of the kidney were long mycelial filaments which had not caused any reaction in the surrounding tissues. This represented a type of saprophytic mycosis perfectly tolerated. A second case was that of a young woman who had had attacks of appendicitis sufficiently abnormal to obscure the diagnosis. Histological examination of the appendix revealed several superficial ulcerations of the mucous membrane with numerous ramifying mycelia. The region of the operation remained tender for two months, but six months afterwards the patient had put on weight and was in perfect health. Durante also encountered a case of true mycelial septicaemia in a woman who, before parturition, was slightly pyrexial; the fever persisted for five days after labour and then disappeared by lysis, and the patient was discharged. Twelve days later she became comatose and died. At the necropsy were found numerous mycelia in the aortic and pulmonary vessels. Threads 4 to 5  $\mu$  in diameter were found lying between the red cells in the vessels, but had not caused thrombosis. On several occasions during the past fifteen years the author has found that neoplasms which had been diagnosed as sarcomata were really due to mycoses. The fungi had a very low virulence, as evidenced by the fact that there was no reaction in the surrounding tissues. He thinks that these infections are probably frequent in their latent form. The septicaemic type in which the mycelium invaded the general circulation appeared to determine accidents rather by their presence than by their virulence. The fact that certain haemophilic mycoses appeared to develop in the general circulation rendered it advisable to make blood cultures on media suitable for mycelia in doubtful cases.

157.

### Pirquet Tests with Different Tuberculins.

A. BRINCHMANN (*Norsk Mag. f. Lægevidensk.*, January, 1928, p. 36) has performed comparative Pirquet tests simultaneously with four different kinds of tuberculin—the official Norwegian preparation, a tuberculin from the Serum Institute in Copenhagen, a German tuberculin (Hoechst's), and a French tuberculin from the Pasteur Institute. Each child examined received five scratches, one serving as a control, and the remainder being used for one each of the four tuberculins. Altogether 89 children were examined, and 342 tests were performed, the reaction being repeated several times in some cases. Variations in the intensity of the reaction provoked by the different tuberculins were observed in several cases, but there were no uniform differences enabling the author to decide that any one tuberculin was superior to the others. There were 68 children who gave a negative or doubtful response, only 21 giving a positive one. With but two exceptions, these 21 children gave a positive reaction to all four tuberculins. But there were only 5 children whose response to the four tuberculins was identical; all the other Pirquet-positive children showed reactions of different severity to the various tuberculins, this difference being in some cases very marked. The author notes that while in hospital practice it is the custom to observe the reaction twenty-four and forty-eight hours after the inoculation, there is usually a delay of two days in general practice before the site of inoculation is examined. In two of his cases a reaction which was positive after twenty-four hours was negative after forty-eight hours, and it would therefore seem that the result of this test should be controlled earlier than is often the case in general practice. The author has failed to find that any one tuberculin is better than others for carrying out the Pirquet test.

158.

### The Spleen in Measles.

E. FRIEDMAN (*Amer. Jour. Dis. Child.*, November, 1927, p. 854) alludes to the paper on this subject by A. Bleyer (*Epitome*, July 3rd, 1926, para. 4), who found the spleen enlarged in the majority of 400 cases of measles at all ages; he records his own observations on 116 cases. In only fourteen patients, or 12 per cent., was any enlargement found. In four cases the enlargement was so slight as to have easily escaped detection under normal circumstances.

It was noteworthy that not a single example of enlarged spleen was found in the severest attacks or in patients with the ordinary complications of measles. The enlargement was most pronounced in the younger children, its degree was independent of the stage of eruption, and the frequency of splenomegaly was almost as great during the early stage as at the height of the eruption. Friedman concludes that an enlarged spleen is not a prominent or frequent occurrence in measles at any stage of its development.

159.

### Otological Complications of Mumps.

O. VOSS (*Deut. med. Woch.*, November 25th, p. 2023, December 2nd, 1927, p. 2074) reviews the literature relating to impairment of hearing or actual deafness on one or both sides and disturbances of equilibrium which occur chiefly in children after the age of 11, but principally in adults suffering from mumps, and records eight cases which came under his own observation in patients aged from 6 to 32. Unlike other writers, who attribute the symptoms to a metastatic labyrinthitis or neuritis, Voss regards these symptoms as due to a serofibrinous meningitis which not infrequently occurs in mumps. Support for this view is to be found in the successful experiments by Kermorgant in producing parotitis in monkeys. In view of the discovery by Kermorgant of spirochaetes, treatment of these complications should consist in injection of arsenical salts.

160.

### Severe Cases of Mumps.

DELCOURT (*Bruxelles-Médical*, November 20th, 1927, p. 89) reports a series of three remarkably severe cases of mumps, one of which terminated fatally. The first was in a boy, aged 13, who developed orchitis; the second was in a woman, aged 22, in whom the attack was complicated by bilateral oophoritis or pancreatitis, as indicated by generalized abdominal pain. Recovery ensued, though the hardness of the parotid persisted. The third case was that of a girl, aged 17, in whom persistent hardness of the parotid was accompanied by high fever. Incision of the gland gave issue to a sanious fluid; gangrene of the parotid followed, and finally myocarditis and death.

161.

### Sewer Gas and Typhoid Fever.

N. SETTE (*Il Policlinico*, Sez. Prat., December 12th, 1927, p. 1813) reports the case of a man, aged 29, who as mechanic in the pneumatic post service was much exposed to inhalation of sewer gas. In the period June-October he had four attacks of continued fever. In the first two attacks the serum tests for typhoid, paratyphoid, and nodulant fever, and the blood culture for the malarial parasite were negative, and the only evidence of typhoid was a dirotic pulse and enlarged spleen. In the third attack rose spots appeared and the fever subsided after injection of Brusebettini's typhoid vaccine. In the fourth attack the typhoid bacillus was recovered from the blood and the infection was apparently cured by an auto-vaccine. Sette maintains that inhalation of sewer gas simultaneously irritates the respiratory and intestinal system, thereby causing a change in the tissue fluids, and so inhibiting the serological reactions.

## Surgery.

### 162. Appendicitis Simulated by Ovarian Haemorrhage.

A. LURJE (*Zentralbl. f. Chir.*, January 7th, 1928, p. 22) refers to several recorded instances of ovarian haemorrhage simulating acute appendicitis, and reports the case of an anaemic unmarried woman, aged 23, who had suffered for a year from moderate pain in the right iliac fossa. She had typical pressure pain at McBurney's point, and dysmenorrhoea. Chronic appendicitis was diagnosed and appendicectomy was performed. The appendix was over four and a half inches long, and the middle third was loosely adherent; no macroscopic changes were seen. Although a little blood was oozing from the lower end of the wound, its source was not evident, and, after removal of the appendix, the abdomen was closed. The patient's temperature fluctuated and her condition caused considerable anxiety for four days, when, on account of symptoms of localized peritonitis in the left flank, the abdomen was reopened. A dirty green exudate was found beneath the caecum and covering the uterus and right tube; the right ovary was normal. The left ovary was as large as a plum; it was dark blue and nodular, and blood

oozed from a pin-head orifice. This ovary was removed, many foul-smelling blood-clots in the pelvis were swabbed out, and the abdomen was closed. Convalescence was tardy, but the patient was discharged eventually in good health. Lurie remarks that the operation for chronic appendicitis coincided accidentally with the rupture of a Graafian follicle. The usual intra-abdominal haemorrhage followed, but appeared so slight that it was disregarded. He adds that the incision was lengthened in order to find the bleeding point, and advises that the incision in appendectomy should be long enough to permit of the examination of adjacent organs, especially of the adnexa.

#### 163. Injury to the Trochanter Minor and Ludloff's Phenomenon.

W. STREBEL (*Klin. Woch.*, January 15th, 1928, p. 123) finds this sign valuable in diagnosis. It is found with avulsion of the small trochanter, and consists in loss of function of the psoas and iliacus. If the affected leg cannot be raised when the patient is in the sitting position, and at the same time the two muscles remain lax, a diagnosis of avulsion of the small trochanter is certain. In one of the author's cases, a boy aged 12, this sign was absent, and the x-ray examination revealed no avulsion but a tear in the small trochanter. In two other patients, aged 15 and 11 respectively, Ludloff's sign was present, and x-ray examinations proved the correctness of the diagnosis. Treatment consists in rest in bed with the leg flexed and rotated outwards. The patients were cured in nineteen days and there were no after-effects.

#### 164. Myeloplax Tumours of the Spino.

M. CAMURATI (*La Chirurgia degli Organi di Movimento*, November, 1927, p. 581) reports a case of myeloplax tumour of the cervical spine, and gives brief details of 18 cases collected by him. In the author's case the tumour contained the usual giant cells. Of the 18 cases the youngest patient was 7 years of age and the oldest 40. In 2 cases the cervical vertebrae were affected, in 6 the dorsal, in 7 the lumbar, in 1 the sacrum, and in 2 the site was not given. Metastases were never noted, but local recurrence was not uncommon. Ossification occurred in 4 cases, and in 3 cases paraplegia persisted in spite of operation. In 14 cases improvement or cure followed removal of the growth. Camurati adds that the exact etiology of these tumours is uncertain; they may represent irregular attempts at repair after injury and correspond with the granular tissue containing giant cells which is sometimes seen in psoudarthrosis.

#### 165. Primary Meningeal Sarcoma.

M. R. CASTEX, J. J. LLAMBIAS and S. BALESTRA (*Rev. Oto-neuro-oftalmol. y de cir. neurol.*, October, 1927, p. 235), who record an illustrative case with a review of the literature, state that in the immense majority of reported cases of meningeal sarcoma the growth is secondary to a central lesion. They have been able to find only five cases, reported by Fox (1883), Hadden (1885), Schrader (1899), and Cassirer-Levy (two cases, 1920), in which, as in their own case, the sarcomatosis was confined to the pia mater. The present case is that of a man, aged 24, who died after an illness of five months' duration, characterized by symptoms of meningitis and terminating with a condition of status epilepticus. The necropsy showed a diffuse thickening of the pia mater of the spinal cord, especially in the dorsal region, and base of the brain. Histologically the condition was found to be a sarcomatous process which had developed in the perivascular connective tissue of the pia. The underlying cord and brain tissue were not affected.

### Therapeutics.

#### 166. Ephedrine Hydrochloride in Whooping-cough.

HAVING noted the relief obtained in five cases of asthma in the young following the administration of ephedrine hydrochloride, W. D. ANDERSON and C. E. HOMAN, jun. (*Amer. Journ. Med. Sci.*, December, 1927, p. 738), concluded that this drug might also give relief in whooping-cough, and they report twenty cases in which it was tried. No cultural or agglutination tests were made, and the cases were diagnosed from the symptoms and general history. Vaccine treatment had been tried without effect in eight of the cases, and five children had received rectal injections of ether in olive oil, with but slight improvement in only two. The ephedrine salt was given orally in a watery solution, the doses being 1/4 grain for children one year old, and 1/8 grain for those younger. In six cases the medication was given at bedtime only, the remaining patients receiving it night and morning and occasionally three times a day. No other treatment was used. The following slightly toxic symptoms were noted in

some of the cases following the administration of the drug: marked abdominal distension, apparent suppression of urine for twelve hours, abdominal pain and discomfort, marked sweating, profuse nasal discharge, epistaxis, and subconjunctival haemorrhage. The authors found that the ephedrine hydrochloride gave relief from spasmodic cough and vomiting in eighteen cases; they attribute it either to the abolition of laryngospasm by the inhibition of a pathological reflex or to direct action on the sympathetic. Some cough persisted, but it was mild and without the characteristics of whooping-cough. No serious toxic symptoms or complications were noted. The authors believe that the drug is most useful during the second stage, and that smaller doses would give relief without any toxic symptoms. The blood pressure showed a slight rise in six out of nine healthy children after ephedrine administration.

#### 167. The Danger of Injections of Saccharated Iron Carbonate Solutions.

R. KRAFT (*Zentralbl. f. Chir.*, December 3rd, 1927, p. 3092) has found that colloidal saccharated iron carbonate solutions, administered intravenously, are of definite value in the treatment of various infections and septic conditions. The injections are often followed by a rapid subsidence of pathological symptoms and a distinct improvement in haematopoiesis. Seventy patients so treated recovered, while in 250 other cases no untoward effects followed the injections. The only adverse signs were sudden transient rigors and pyrexia. Recently, however, Kraft has had two fatal cases, showing that this treatment is not free from danger. The first patient, aged 18, had appendix perforation, followed by peritonitis and phlegmonous changes in the caecum. Abscesses followed in the abdominal and pelvic cavities, and, as bronchopneumonia ensued, 80 c.cm. of saccharated iron carbonate solution was injected. This was followed by a severe rigor and signs of circulatory failure, and four hours later the patient died from heart failure. The second patient, a man aged 56, had undergone gastro-jejunostomy for gastric carcinoma; this was followed by symptoms of commencing pneumonia. An injection of 100 c.cm. of saccharated iron carbonate solution was given, and fifteen minutes later there was a severe rigor lasting twelve minutes. Two hours later the patient lost consciousness, became dyspnoeic, the circulation gradually failed, and he died in ten hours. Kraft states that the saccharated iron solution ought to be perfectly clear reddish brown in colour, and he recommends a 4 per cent. colloidal solution in twice-distilled water.

#### 168. Treatment of Ringworm by Thallium Acetate.

D. M. LEVY (*Nederl. Tijdschr. v. Geneesk.*, December 17th, 1927, p. 2611) states that this method was first introduced by Cicero, and later employed by Buschke, Peter (354 cases), and Trokno (104 cases) with invariable success. The present author records his own experiences of this method in twenty-six cases of ringworm in patients aged from 3 to 16 years. The drug was given by the mouth, according to Buschke's recommendation, in doses of 8 mg. for each kilo of body weight. The hairs began to fall out in from two to three weeks; in a month's time the whole scalp became bald, and after another four weeks a fresh growth of hair appeared. The hair of the scalp only was affected. No complications occurred except in one child who developed a generalized eruption of large and small macules accompanied by nephritis; recovery followed in three weeks' time.

169. W. G. BRONSTEIN (*Med. Klinik.*, December 2nd, 1927, p. 1854) reports 94 cases of ringworm treated in one year by thallium acetate, and describes experiments on animals. He finds that young children stand the treatment better than older ones, and that severe albuminuria only occurs through a miscalculation of dosage. He states that no departure from the normal is discernible in children a year later. His method is the administration of 0.008 gram of thallium acetate for each kilo of body weight in water before food in the morning; he only treats children between the ages of 1 and 14. The hair comes out fourteen to sixteen days later, and growth begins again in four to six weeks. Comparing this treatment with x-rays the author finds it to be more often successful, shorter, less unpleasant, and followed by fewer complications.

#### 170. Liver Diet in Nephrosis.

O. FORGES (*Wien. klin. Woch.*, December 29th, 1927, p. 1640) reports a case of pernicious anaemia with extensive oedema which demonstrates the diuretic action of liver diet. The patient, who had had a course of arsenic a month previously, had a severe relapse; she was very anaemic and had extensive oedema. Arsenic injections produced an improvement in the blood state and also in the general health, but without reduction of the oedema. Enphyllin and theocin produced

distinct diuresis, the weight being reduced by 4 lb., when it became stationary. Liver diet was then commenced, and after three days considerable diuresis occurred, the amount of urine passed daily rising to 4 litres. At the end of a fortnight the patient's weight had been reduced by 1½ st., while the erythrocyte count and the haemoglobin index improved but slowly, so that the diuresis could not be attributed to blood regeneration. When the oedema had disappeared entirely a rapid restitution of the blood occurred. These observations suggest that the diuretic action of liver diet in dropsy might have other origins. In two cases of heart failure with hepatic cirrhosis, generalized oedema, and severe ascites, the liver diet prevented recurrence of ascites after paracentesis, when all diuretics had failed. In a case of moderate calcific oedema, associated with secondary anaemia following ulcerative colitis, the weight was reduced by 6½ lb. in eight days, oedema disappeared, and continuous improvement in the blood condition followed. A case of diabetes complicating alcoholic hepatic cirrhosis with slight ascites was cured by liver diet. In four days the weight was reduced by 6½ lb.; after five days' treatment the liver diet was discontinued, and six days later the patient's weight had increased by 6½ lb. The patient's general condition improved rapidly; appetite returned and the glycosuria was inhibited. Porges agrees that the liver produces a hormone that regulates the excretion of water; this substance is not destroyed by cooking, and is active when administered orally.

#### 171. Glucose Medication.

ADMITTING the great value of intravenous glucose injections in anaemia and toxæmia in consequence of the supply of calories, the relief of nausea, the economizing of proteins, and the completing of the combustion of fats, W. E. ROBERTSON, A. E. OLIENSIS, and D. STEIN (*Med. Journ. and Record*, December 7th, 1927, p. 654) have tried to determine the factors responsible for the untoward reactions and deaths which occasionally follow this treatment. They find that a concentrated solution affords greater safety and freedom from reactions than weaker concentrations with larger volumes; the rate of injection and the temperature of the solution are also important factors. They advocate the injection by gravity at body temperature of 108 grams of dextrose in 180 c.c.m. of freshly prepared sterile salt solution, the time taken being never less than thirty minutes. With this technique no reactions occurred in fourteen consecutive cases, although the patients were seriously ill, and it was found that a severely damaged cardio-vascular system was no contraindication. The authors conclude that untoward results are due to too rapid a rate of injection, too large a volume of fluid, and an improper temperature of the solution. The use of distilled water is deprecated, since it has been shown to produce haemolysis and occlusion of the coronary arteries and peripheral vessels.

### Radiology.

#### 172. Radium Implantation in Oesophageal Cancer.

J. MUIR (*Laryngoscope*, September, 1927, p. 660) recognizes three drawbacks to the use of radium in oesophageal cancer: (1) the difficulty of placing it accurately; (2) the practical impossibility of maintaining it in position long enough to be effective; and (3) the great danger of burning the tissues, which will induce sloughing and fistula into the mediastinum, invariably a fatal accident. He has elaborated a technique of radium implantation through a specially designed oesophagoscope. The field of operation is illuminated and an implanter passed through the tube. The radioactive source employed is a removable platinum radon seed, which offers the double advantage of being so secured that it will not undergo necrosis, and the possibility of removal by means of an attached thread. The entire procedure is facilitated by the use of the fluoroscope, though this is not essential. The results in a small series of cases so far treated by this method have been gratifying.

#### 173. Radiotherapy of Asthma and Spasmodic Coryza.

P. VALLÉRY-RADOT, P. GIBERT, P. BLAMOUTIER, and F. CLAUDE (*Presse Méd.*, October 5th, 1927, p. 1201) have employed x-ray treatment in cases of asthma and spasmodic coryza with some good results, and cite supporting evidence from the literature. The methods include irradiation of the thorax and spleen, singly or combined, and applications have been made to the thyroid in asthma associated with exophthalmic goitre. The results have been very variable; there is often a more or less transient improvement. The authors quote statistics of six investigators who used thoracic irradiation; these show approximately 30 per cent. of cures, 43 per cent. of cases more or less relieved, and 27 per cent. of failures. On the other hand, splenic x-ray treatment appears

to have given approximately 82 per cent. of cases cured or improved and 16 per cent. of failures. Reference is made to the paper by S. Gilbert Scott (*BRITISH MEDICAL JOURNAL*, June 5th, 1926, p. 939), who, in 21 cases treated by combined thoracic and splenic irradiation, obtained very good results in all but one. The present authors treated 64 patients of both sexes, of whom 31 had asthma only, 8 spasmodic coryza alone, and 25 had both affections. Almost all the patients were adults, and the cases were not selected. They report 30 per cent. cured, 25 per cent. improved, and 45 per cent. were failures, or showed only temporary improvement; 26.5 per cent. of these were total failures. Some patients remained cured or greatly improved for fifteen or eighteen months. The authors believe that their best results followed combined thoracic and splenic irradiation. Twelve treatments may be necessary before a case can be regarded as a success or a failure, and many patients have improved only after 6, 8, or 10 irradiations. In apparently similar cases the treatment succeeded in one patient and failed in another.

#### 174. Radiological Examination of the Trachea.

M. SGALTZER (*Wien. klin. Woch.*, September 15th, 1927, p. 1181) states that accurate information regarding alterations in the position of the trachea may be obtained radiographically if the patient is examined in the lateral position, with the shoulders thrown well back, as well as in the antero-posterior position. The information thus obtained is very useful in cases of enlarged thyroid when surgical treatment is under consideration; it will assist in differentiating dyspnoea directly due to pressure on the trachea from that due to cardiac weakness, so that operation on an enlarged thyroid which is not really affecting the trachea may be avoided when the heart is embarrassed from toxic or other causes. In some cases goitres of very slow growth may compress the trachea to a considerable extent without producing respiratory symptoms; in these an x-ray examination will demonstrate the need for an operation if the risk is to be eliminated of sudden acute dyspnoea or even suffocation from obliteration of the lumen of the trachea, which such conditions as mild tracheitis might produce. Sgaltzer adds that screening will also show the size and position of a substernal goitre, as well as the range of mobility of the trachea on coughing and deglutition; this information is valuable, since the presence of extensive adhesions considerably increases the difficulty of thyroidectomy. The extent to which pressure has produced atrophy of the rings of the trachea, with consequent weakness of the tracheal wall, may be seen from the amount of bulging or retraction of the tracheal wall produced when forcible expiration or inspiration is attempted while the external respiratory passages are closed. This atrophy is an important indication for surgical treatment.

#### 175. Intravenous and Peroral Methods in Cholecystography.

T. SENDTNER-VOELDERNDORFF (*Med. Klinik*, September 9th, 1927, p. 1374) contrasts the two methods of filling the gall bladder in cholecystography, and emphasizes the value of the peroral method. In this he maintains there is less danger to the patient; it is easier, and gives equally good results. He uses a preparation called "videofol," either in the form of pills or of capsules containing 0.5 gram each, the dose being one pill per 10 kilograms of body weight. These pills, in common with all tetraloid preparations, do not keep well. The patient should have a light meal and an enema in the evening, after which the pills should be given with cream. This not only disguises the pills, but, as an emulsion of fat, assists in emptying the gall bladder. The patient then fasts for twelve hours, after which the x-ray examination takes place. The author adds that he has never observed any ill effects to the patient result from this method, and in 36 out of 50 cases the gall bladder was made distinctly visible.

### Obstetrics and Gynaecology.

#### 176. Physiotherapy in the Treatment of Salpingo-oöphoritis.

H. DAUSSET and A. CHENILLEAU (*Paris Méd.*, December 17th, 1927, p. 499) describe the treatment of salpingo-oöphoritis in the physiotherapeutic department of the Hôtel-Dieu in Paris. The treatment of choice in tuberculous cases is heliotherapy and ultra-violet irradiation. Hydrotherapy, diathermy, and vaccines are recommended for all other cases, irrespective of etiology, though vaccines are said to be particularly valuable in the gonococcal group, which is otherwise very resistant to treatment. The hydrotherapeutic procedures include vaginal irrigation at minimal pressure with 100 litres of water at 104° to 112° F., continued for at least half an hour, spraying of the abdomen and loins with water at a temperature of 112° F.,

a quick shower lasting half a minute to a minute, commencing with a temperature of 100° F. and cooling down to 86°. Another method is the administration of a hot vaginal douche, 194° to 108° F., under water in a bath at blood heat; about 100 litres of water are given in ten minutes, and a shower bath concludes the treatment. For diathermy an apparatus yielding 3.5 to 4 amperes is used. The electrodes are placed over the abdomen and lumbosacral regions, with or without another in the vagina, or one may be introduced into the rectum and the other placed over the abdominal wall. Bipolar electrocoagulation with Walter's apparatus and a current of 200 to 400 milliamperes is said to be of particular value in subcutaneous cases. Heliotherapy may be general or localized over the abdomen. Ultra-violet irradiation is applied by means of a mercury vapour or an arc lamp; for local treatment alone a 20-ampere Bénard lamp is used, while intravaginal application is effected by an arc lamp and a vaginal speculum. Local irradiation with infra-red rays is also used, and with the total rays of a metal filament lamp of 2,000 to 3,000 candle power. Gynecological massage, direct or indirect, and active movements, such as abduction and adduction at the hips, complete the course.

#### 177. Large Ovarian Cyst.

C. R. BALTAR (*Revista Clinica de Bilbao*, September, 1927, p. 419) records the case of a woman, aged 42, who had passed the menopause nine months previously. For a year she had had pain in the lower abdomen and a feeling of weight in the gastric region. Gradual increase in the size of the abdomen occurred, and later became rapid. The circumference of the abdomen was 44 inches; it was wholly occupied by a tumour, which also invaded the base of the chest, pushing forward the xiphisternum. Through the posterior vaginal fornix a cystic swelling could be felt. The diagnosis of ovarian cyst was made. In order to reduce the pressure effects paracentesis of the cyst was performed under local anaesthesia and a large quantity of blackish pseudo-mucinous fluid, typical of ovarian cyst, was evacuated. The patient experienced much relief from the evacuation of this fluid. The abdomen was later opened through a median subumbilical incision, which had to be lengthened to deliver the tumour, the pedicle being ligatured with catgut. The post-operative course was uneventful. The weight of the extirpated tumour was 48 lb., which with that of the 25 pints of fluid evacuated made a total weight of 92 lb.

#### 178. Trial Labour.

H. BAILEY and H. C. WILLIAMSON (*Journ. Amer. Med. Assoc.*, December 17th, 1927, p. 2085) recall that the primary indication for Caesarean section is pelvic contraction, or disproportion between the size of the child and the mother's pelvis. The mortality from Caesarean section performed after protracted labour has been from 10 to 15 per cent., so that a trial labour in cases of pelvic contraction has not been justified; with the recent development of the low cervical Caesarean section, which decreases the danger to the mother, a primary test of labour is, however, permissible. As regards contraction, they recognize three types: (1) The normal pelvis, with an estimated true conjugate of more than 9.5 cm. or with a bischiatric diameter of more than 7 cm. (2) The relatively contracted pelvis, with a true conjugate of from 7.5 to 9.5 cm. in the generally contracted pelvis, from 7 to 9 cm. in the flat pelvis, and from 6 to 7 cm. as an outlet measurement in the funnel-shaped pelvis. (3) The absolutely contracted pelvis, where there is a true conjugate of under 7.5 cm. in the generally contracted, under 7 cm. in the flat, and under 6 cm. for the bischiatric diameter in the funnel-shaped pelvis. Of 11,491 deliveries under their control during a period of five years there were only five cases of absolute contraction and 671 cases of relative contraction, as estimated by these measurements. With the exception of the five cases of absolute contraction and twenty-four elective Caesarean sections, the women were given a trial labour. In 65 per cent. of these delivery was spontaneous. The remainder were delivered by operation, and of these 9.9 per cent. required Caesarean section. No maternal deaths followed the sections, and in the entire series there were only three deaths. The authors conclude, therefore, that it is advisable to give all patients with relatively contracted pelvis a trial labour. The unknown factor in every labour is the malleability and compressibility of the foetal head and the force of the labour pains. Many foetal heads which are unengaged before labour rapidly mould and enter the pelvis at the onset of good contractions. The patient should be permitted to have a trial labour of at least twelve hours of hard pains, and this should be conducted without vaginal or rectal examinations, in order that the vaginal tract may be free from infection should operative delivery become necessary. If, at the end of this time, the foetal head has not entered the pelvic canal, as can be ascertained by means of the Pawlik grip, a low Caesarean section should be performed: if the head has

entered the canal the patient will either deliver herself spontaneously or should be delivered by forceps. The authors believe that a trial labour is more complete if it is permitted to continue after the rupture of the membranes. Even if the foetal head becomes engaged after strong pains labour is not allowed to continue until the patient is exhausted or until harmful pressure on the soft parts may occur. Spontaneous delivery, they add, in relatively contracted pelvis can be accomplished in a labour that is no longer than normal. Trial labour reduced the incidence of Caesarean section in their 676 cases to 14 per cent., and there were no deaths; the gross foetal mortality was 6.2 per cent.

## Pathology.

#### 179. Precipitable Substances derived from Typhoid Bacilli.

J. FURTH and K. LANDSTEINER (*Journ. Exper. Med.*, January, 1928, p. 171) have isolated two serologically active protein substances from *B. typhosus*, and another substance, chiefly of carbohydrate nature, that reacts as a specific precipitable body. The first protein substance was extracted from the bacilli with 75 per cent. alcohol; the second protein substance was obtained by saline extraction of the bacilli remaining over from the first process. The carbohydrate substance was obtained by digesting with trypsin bacilli which had been extracted with alcohol; the material resulting from digestion was made strongly alkaline and precipitated with alcohol. The protein substances were destroyed by tryptic digestion and by treatment with antiferritin; the carbohydrate substance, on the other hand, resisted both these methods of digestion. Serologically, it appears that the carbohydrate substance is responsible for the specific precipitation obtained with an immune typhoid serum. Similar specific precipitable substances were obtained from *B. paratyphosus* B, *B. enteritidis*, and *B. proteus*.

#### 180. Bactericidal Power of the Blood after Ultra-violet Irradiation.

L. COLEBROOK, A. EIDINOW, and L. HILL concluded from experiments that the blood of animals submitted to irradiation with ultra-violet light has an increased bactericidal power, the increase reaching a maximum one hour after exposure and being followed by a return to normal in three hours. I. TATARANU (*C. R. Soc. de Biologie*, January 4th, 1928, p. 1737) has repeated these experiments. Rabbits were exposed to rays from a quartz lamp (4 amperes, 110 volts) for thirty minutes at a distance of 40 cm.; the part of the body exposed was shaved twenty-four hours previously. Blood was withdrawn from the auricular or saphenous vein before every exposure, and half an hour, three-quarters of an hour, one, two, six, and twenty-four hours after it. The blood was defibrinated, and tested immediately for its bactericidal action on *Staphylococcus aureus*. The technique employed differed from Wright's only in that the organisms were suspended in Ringer's solution instead of in saline, the latter having, as has been shown by numerous workers, a disinfectant action on bacteria. Tataranu made experiments on ten rabbits, but failed to detect any difference in the bactericidal power of the blood after exposure to the ultra-violet rays.

#### 181. Varieties of Immunization.

E. SARGENT, L. PARROT, A. DONATIEN, and F. LESTOQUARD (*Arch. Inst. Pasteur d'Algérie*, vol. v, No. 4, 1927, p. 469) observe that from the standpoint of immunity infectious diseases can be divided into two groups. In one, acute and cyclic, a true immunity is conferred on the organism; this is characterized by a complete disappearance of the causal microbes and by a resistance of the cured subjects to all reinfection. Such diseases include small-pox, scarlet fever, and measles. In the other group, after an initial period of invasion marked by reactions, an equilibrium is established between the organic defence and the microbic attack, the patient becoming to all appearance cured, though the aggressive micro-organisms still persist. Syphilis, tuberculosis, and malaria are examples of such infections. The authors assert that the terms "relative immunity" and "immunity tolerance" are really incorrect, as they express a part only of the phenomenon of immunity—namely, the lauring of the organism to infection—and omit the other essential characteristic of resistance to reinfection. The term "premunition" is suggested as being more appropriate, its definition indicating "guarding by precaution." Premunitive vaccination would be descriptive of such measures as antituberculous vaccination with bacillus Calmette-Guérin vaccine. Five methods of premunizing are described. The authors maintain that, though still theoretical, premunition can be a useful therapeutic measure, and that further work is necessary to perfect the present methods and to discover new ones.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 162. Sodium Salicylate Poisoning following Injections.

E. G. JORGENSEN (*Ugeskrift for Læger*, January 12th, 1928, p. 31) records the case of a woman, aged 45, who received three intravenous injections of sodium salicylate (5 c.cm. of a 20 per cent. solution at each injection, without any abnormal local or general reaction). A week after the third injection the fourth and last injection of 5 c.cm. of a 20 per cent. solution was given one morning without any difficulty, but two or three hours later the patient complained of headache, tinnitus, shivering, and severe perspiration. Her face, hands, and feet rapidly became oedematous; she was hardly recognizable, and her hands were bloated and shapeless. During the afternoon of the same day an urticarial erythema broke out, being most marked on the face and lower limbs; some petechiae appeared on the inner side of both thighs. In the evening she suffered from nausea and repeated vomiting, but there was no diarrhoea or disturbance of micturition. Respiration was somewhat laboured and rapid, but there was no hoarseness or cough. She was very frightened and restless, and complained of severe palpitation of the heart; the pulse was quick, soft, and regular; the temperature was normal and the urine contained no albumin, blood, or sugar. The oedema, rash, and headache disappeared after about twenty-four hours. The patient had previously taken large doses of aspirin without ill effects, and the first three injections of sodium salicylate had been well tolerated. So far as the treatment of the varicose veins was concerned, the four injections were successful. Discussing the possibility of this form of poisoning, the author remarks that this is probably the first case to be recorded in Denmark, and he notes that Sicard and Gaugler have observed only two cases among several thousands of patients given intravenous injections of sodium salicylate. In one case urticaria developed directly after the injection, in the other twenty-four hours subsequently.

### 163. Diphtheria Without Membrane.

M. NATHAN (*Presse Med.*, December 3rd, 1927, p. 1476) states that diphtheria without definite membrane is most frequently met with in infants below the age of 6 months, when it appears in the form of otitis, inflammation of the umbilicus, and ulcers behind the ears, but chiefly as rhinorrhoea. Although the nasal localization of diphtheria was recognized by Bretonneau, who gave his name to the disease, the only form of nasal diphtheria recognized for a long period was that associated with a blood-stained membranous discharge. It was not until 1898 that Huthnel drew attention to the onset of diphtheria bacilli in the purulent nasal discharge of young children. Later Marfan, Ribadeau-Dumas, and pupils showed that even the mildest form of nasal large might contain diphtheria bacilli. The apparently cases, however, may develop croup, broncho-pneumonia, more frequently, a severe form of infantile diarrhoea, the nature of which may escape recognition. The clinical signs of this form of nasal diphtheria are not distinctive, the diagnosis can only be made by bacteriological examination.

### Pulse Wave Velocity.

EYERHOLM (*Acta Med. Scand.*, December 12th, 1927, p. 323) uses the pulse wave velocity in certain pathological conditions, and remarks that both the blood pressure and pulse velocity show individual variations, particularly as regards age and sex. Difficulty has been experienced in getting normal values for these, but a study of 90 healthy persons showed that the normal blood pressure should not be over than 130 mm. of mercury or lower than 80 mm., the normal pulse velocity being 7 to 8 metres a second. Chronic arthritis and arterio-sclerosis are the principal causes of hypertension. Tests of 5 cases (4 men and 1 woman) of chronic arthritis with hypertension showed that in this condition the pulse velocity is increased, but that the pressure and velocity are not proportionate. In 20 cases (9 male and 11 female) arterio-sclerosis with hypertension the pulse velocity was raised, and, as a rule, corresponded to a high blood pressure. In 26 individuals (18 men and 8 women) with arterio-sclerosis without hypertension the pulse velocity was greater than in individuals of the same age class without arterio-sclerosis. In Basedow's disease, neurosis cordis, and compensated valvular disorders the velocity of the pulse showed no pronounced pathological changes. The

results in arrhythmias were inconclusive, as many of the patients had other complications. Eyerholm asserts that the clinician may be assisted by ascertaining the pulse wave velocity, when, after ordinary blood pressure measurement, there is a doubt as to the presence of hypertension. If, for instance, in chronic nephritis or supposed arterio-sclerosis a systolic blood pressure is found which varies between 130 and 150 mm. of mercury, a pulse wave velocity of  $9\frac{1}{2}$  to 10 metres a second, or more, will practically be evidence of the presence of hypertension, and at any rate provide certainty that the circulation conditions are pathologically altered. In over a thousand examinations of about 200 cases such a velocity occurred only in patients with hypertension.

### 185. The Ocular Manifestations of Epidemic Encephalitis.

ACCORDING to G. W. VANDEGRIFF (*Med. Journ. and Record*, December 21st, 1927, p. 723) paralysis of convergence is a very common prodromal symptom of epidemic encephalitis; the patient complains of double vision, especially on reading. Instead of paralysis of convergence there may be a paralysis of a lateral muscle, usually the external rectus, with homonymous diplopia, or a paralysis of divergence with the same diplopia without paralysis of either external rectus. While ptosis may accompany any of these paralyzes it is more likely to be a later development. Fundus examination reveals marked fullness of the central vein and its branches. Optic neuritis is rare and choked disc develops only as a result of very high intracranial pressure. As the severity of the disease increases, photophobia and visual irritability appear. The usual ocular paralysis is of the third and sixth nerves, separately or in various combinations; abducens and levator palsies are common. Fourth nerve paralysis is rare. Associated with the ocular palsies may be disturbance of other cranial nerves, especially the fifth, seventh, ninth, and tenth, and any or all of these may be accompanied by sympathetic disturbance. The pupillary reactions show a great variety; one or both eyes may be involved, and, when binocular, the phenomena may be similar or dissimilar. In 35 per cent. there was defective pupillary light react on with irregularity and inequality. The Argyll Robertson pupil may be present, though more frequently the convergence is absent as well as the light reaction. As the acute encephalitis subsides the ocular symptom may disappear or persist, or there may be a recurrence of ocular symptoms after periods of absence or quiescence. The value of treatment is doubtful, but bismuth salicylate intramuscularly and sodium iodide internally may be of benefit in some cases. In the later stage a cosmetic operation may be needed.

## Surgery.

### 186. Etiology of Congenital Torticollis.

A. HELLSTADIUS (*Acta Chir. Scand.*, December 24th, 1927, p. 586) has collected the 23 cases of congenital torticollis observed in the period 1915-25 in a children's hospital in Gothenburg. Among these there were two with a family history of torticollis, the younger sister of one patient and the uncle of another having also suffered from it. It was significant that in as many as 15 of these cases the confinements had been abnormal; there had been a breech presentation in 13 cases, and forceps had been required in 2 other cases. With the exception of 2 out of the 23 cases, fairly accurate data were obtainable as to the time at which the torticollis had begun to develop. Only in 5 cases was this condition present at birth; in 5 other cases it appeared during the first year of life, and in the remaining cases after an interval ranging from one to twelve years. The facts that in several cases the disease appeared many years after birth and developed gradually are, in the author's opinion, opposed to the theory that torticollis is of foetal origin. There were 16 cases in which the torticollis was associated with asymmetry of the face, but the degree of the one condition was not proportional to that of the other, and the author adds that the type of asymmetry of the face most often found in association with torticollis may also exist in the absence of this condition. He concludes that, although the frequency of abnormal confinements (notably breech presentations) is exceptionally high in association with torticollis, the most favoured theory as to its origin hinges on hereditary factors.

## 187. Empyema in Children.

C. E. FARR and M. I. LEVINE (*Surg., Gynecol. and Obstet.*, January, 1928, p. 79) review a series of 371 cases of empyema in children especially with regard to age, incidence, and organisms. All were treated surgically, and definitely diagnosed by aspiration and  $x$  rays. At least 92 per cent. were secondary to an attack of pneumonia, the highest incidence occurring in the second year of life. The death rate reached its highest point during the first year of life, and steadily declined after the second year until the age of 6; after this death seldom occurred save as the result of some complication, and it was not directly due to the empyema itself. In the first year the pneumococcus was responsible for 22 per cent. of the cases, whereas it subsequently averaged about 60 per cent. During the first year streptococcal and mixed infections showed a higher percentage. Treatment consisted chiefly in a primary aspiration to ascertain the nature of the pus, followed by open draining by resection or intercostal incision with open tube. The best time for operation depends entirely upon the general condition of each individual case, since the gravity of the prognosis is increased if an operation is undertaken before the pus has become thick and the cavity well walled off. Recurrence seldom results if free drainage is established and maintained until the wound closes.

## 188. Renal Distortion.

G. W. BELCHER (*Journ. Amer. Med. Assoc.*, December 24th, 1927, p. 2166) considers the relation of renal distortion to nephralgia, a distorted kidney being one in which a part or the whole of the pelvis is twisted, tilted, or bent from the normal position. When such a condition, as shown by the pyelogram, is associated with nephralgia and the pain is induced by distension of the renal pelvis or rotor the distortion of the kidney has to be considered as a possible factor in its production unless some other pathological condition of the urinary tract is present. Renal distortion may only be discovered by chance, since it does not usually cause any symptoms; in some cases nephralgia results, which may be intermittent and postural or be caused by the encroachment of neighbouring viscera, commencing hydronephrosis, post-operative cicatrization, or arterio-sclerosis. Belcher states that care must be exercised in interpreting the pyelograms, especially if there has been previous nephrotomy or nephropexy; if there are any other associated disturbing conditions they should be treated before operating for the relief of the pain. In any event the patient should be under observation for a considerable time and other measures tried. If an operation is to be performed the author advises decapsulation and section of the nerves of the renal pedicle should the kidney function be fairly normal; but in the presence of severe symptoms and marked atrophy nephrectomy with removal of the capsule is recommended.

## 189. Diagnosis of Congenital Dislocation of the Hip.

In a number of cases of congenital dislocation of the hip-joint Lorenz's bloodless method of treatment fails to effect a cure because of a constriction in the capsule, which may be hour-glass in shape or due to bands or the ilio-psoas muscle, and which it may be impossible to diagnose clinically or by ordinary radiological methods. H. BRONNER (*Zentralbl. f. Chir.*, December 10th, 1927, p. 3237) has found the injection of air into the capsule of considerable diagnostic value, especially in older patients. The position of the acetabulum is ascertained by an  $x$ -ray examination and the thigh anaesthetized locally with novocain at this level at the border of the tensor fasciae femoris and sartorius. A 15 cm. needle is introduced at an angle of about 45 degrees to the vertical, pointing towards the centre of the acetabulum, the direction being, if necessary, controlled by screening. When the resistance of the floor of the acetabulum is reached the needle is pressed firmly home to ensure piercing the anterior part of the capsule, and then withdrawn slightly, before filtered air is slowly and carefully injected; the quantity and pressure are controlled by the subjective sensations of the patient as in pyelography. A series of skiagrams is taken at different stages of the injection and with the pelvis and leg in various positions, so as to obtain even distribution of the air and the best image of the acetabulum. Bronner maintains that by this method, found to be free from danger, it is possible to estimate the extensibility of the capsule and the relations of the surrounding soft parts to it, which is of considerable prognostic value. The results compare favourably with those obtained by the iodipin injection method recently advocated by Slevens, certain disadvantages of the latter method being avoided—such as the need for using a wide-bore needle or cannula, the risk of obscuring the skiagrams by spilling an opaque fluid into the surrounding tissues, and the slow absorption of the injected fluid which may interfere with subsequent skiagrams.

## Therapeutics.

## 190. Sodium Chloride Injections in Acute Intestinal Obstruction.

A. GOSSET, L. BINET, and D. PETIT-DUTAILLIS (*Presse Méd.*, January 7th, 1928, p. 17) conclude, from a study of the evidence obtained by French, British, and American research workers, that the increasing toxæmia from the moment when obstruction occurs is due to the using up of the sodium chloride in the blood in the course of the conversion of toxins into some innocuous compound. They give experimental figures to show the decrease of sodium chloride in the blood after experimental tying of the intestine in dogs, and record how, in other experimental cases where the intravenous administration of hypertonic saline solution has kept the sodium chloride content of the blood at the normal level, the life of the animal has been prolonged beyond the usual three or four days after operation to as much as twenty-eight to thirty days. The authors think that the diminution of the sodium chloride content of the blood is a far more important factor in cases of intestinal obstruction than the mere loss of fluid by vomiting; moreover, they show how the urea and residual nitrogen content of the blood constantly rises as that of the sodium chloride falls. They describe cases of acute intestinal obstruction in human beings where severe toxic symptoms had supervened in spite of surgical relief of the condition, and in which the administration of hypertonic sodium chloride intravenously had brought the patients from a moribund to a convalescent state. In one series of cases reported in America there was an operative mortality of only 11.1 per cent., as compared with 50 per cent. in another series not treated by this method. The authors consider that intravenous medication should be begun immediately after operation; the longer the delay the less is the likelihood of success. The maximum dose is given as 1 gram per kilo of body weight during forty-eight hours (that is, about 70 grams for a man of average weight), but a total quantity of about 20 grams is said to be sufficient to make good the loss of body fluid. Subcutaneous administration of 1 litre of physiological serum should be given during the same forty-eight hours. Although stronger concentrations have been used without mishap it is recommended that a 10 per cent. hypertonic saline solution should be employed, and that not more than 30 c.cm. should be given at a time.

## 191. Epidural Administration of Drugs.

W. SCHOENFELD (*Urol. and Cut. Rev.*, November, 1927, p. 710) states that the epidural method of injecting drugs was introduced into medical practice by Cathelin more than twenty-five years ago, since when it has been used extensively for the introduction of anaesthetics, especially cocaine and novocain, of normal saline solution in the treatment of nocturnal oncosis, and of yohimbine in the treatment of impotence. Schoenfeld now discusses the question whether the epidural administration of bromides, iodides, and salvarsan is useful in practice, and comes to the following conclusions. Solutions of 3 to 10 per cent. of sodium bromide or iodide when introduced epidurally in doses of 30 c.cm. pass into the spinal fluid. Therapeutic results therefore may be expected in those diseases in which large quantities of bromides or iodides are required. Little is to be expected from the epidural administration of salvarsan, since the passage of this drug into the spinal fluid cannot be detected after epidural injection.

## 192. Insulin Treatment of Diabetes.

M. LABBÉ (*Ann. de Méd.*, December, 1927, p. 563) discusses the insulin treatment of diabetes as regards the indications, technique, and results. In grave diabetes with nitrogenous denutrition and acidosis two methods of procedure may be followed. By a calculation of the weight and height of the patient a diet is instituted which provides the necessary calories, and insulin is given in doses approximately calculated on the tolerance for carbohydrates and on the hypothesis that one clinical unit of insulin utilizes about 1 gram of carbohydrate. Labbé prefers to follow another method. Commencing with a diet of green vegetables, insulin is given in small doses of 10 to 20 units a day. At the end of three or four days the diet is gradually augmented, and, if the glycosuria reappears or increases, the insulin dosage is progressively increased from 30 to even 100 units daily. When the nutritive equilibrium has been established this should be maintained and the patient kept without hyperglycaemia and acidosis by a suitable diet and insulin dosage. In diabetic coma, which is preventable by a careful adherence to treatment, heroic measures are necessary, and 20 units of insulin should be injected every half-hour. When improvement results the time interval is gradually increased until only 60 units a day are given. In order to ensure rapidity of

action the first injections should be intravenous, and the subsequent ones intramuscular or subcutaneous. Owing to the excess of insulin hypoglycaemic coma may supervene, in which case injections of 5 per cent. glucose are required. As a rule, insulin is not necessary in diabetes without denuitrition, and should only be given in severe cases in moderate doses of 10 to 20 units daily; there are no specific contraindications to its use. The injections are usually given subcutaneously as a slow absorption is desirable, or intramuscularly; the intravenous route is employed only in urgent cases. Other methods, as by the mouth or nares, in suppositories, enemata, or injections, are inefficacious. Abscess formation and dermatitis may occur during treatment, but the serious complications are the consequence of hypoglycaemia due to too strong a dosage. Though the favourable results following a persevering and energetic treatment are encouraging no authentic case of cure has yet been reported. Labbé believes that no case of true diabetes is refractory to insulin treatment.

#### 193. Therapeutic Uses of Carbon Dioxide.

J. C. WHITE and L. M. HURNTAL (*Boston Med. and Surg. Journ.*, December 15th, 1927, p. 1117) review the present therapeutic status of carbon dioxide, especially with regard to research during the past seven years in its use as a respiratory stimulant. In concentrations varying from 5 to 7 per cent. its use is recommended for all purposes where a respiratory stimulant is needed, but in cases of carbon monoxide poisoning it should be given in oxygen rather than in atmospheric air, since by this means the dissociation of carbon monoxide haemoglobin is more rapidly brought about. The authors mention its value in the elimination of volatile drugs—as, for example, in de-etherization after anaesthesia by the closed method and in alcoholic intoxication—and as a means of producing smooth and rapid induction in a struggling patient or in one who persistently holds his breath. In combating respiratory failure after overdoses of depressant drugs—for example, morphine or veronal—it has been used with success, as also in the treatment of prolonged ileus and in the resuscitation of the newborn. Owing to its action in increasing respiratory effort it aids expansion of the atelectatic lung, and its use in the obliteration of large empyema cavities is recommended as an accessory to the usual breathing exercises. The authors consider that there is practically no contraindication to its use in sufficient quantities to produce moderate degrees of hyperpnoea and to supplement without replacing other therapeutic measures.

### Disease in Childhood.

#### 194. Treatment of Diabetes in Children.

K. U. TOVERUD (*Brit. Journ. Child. Dis.*, July-September, p. 185, and October-December, 1927, p. 157) records his observations on 47 children suffering from diabetes mellitus, who had been treated with insulin at the pediatric clinic of the State Hospital of Norway during the period April, 1923, to April, 1926, and had been kept under observation ever since. As regards the etiology the hereditary factor did not appear to be of importance, since it was present in only 8 cases (17 per cent.), whereas acute infections immediately preceding the diabetes were present in 12 cases (26 per cent.). All the children under insulin treatment developed quite normally both mentally and physically, provided they were kept under strict control. In 7 cases the carbohydrate tolerance was stationary or even increased with insulin. In all these cases the control of the diet was invariably very strict and there were very few recurrent infections. In the other patients, however, the carbohydrate tolerance decreased owing to lack of control over the diet and acute recurrent infections—the two main factors in the series which were of greatest importance in decreasing the child's carbohydrate tolerance. Of the 47 children, 17 (36 per cent.) died, 5 in coma closely connected with an infection, and one in coma just after fracture of the femur. In 4 cases the children refused insulin treatment at home, and in the remaining 7 cases little attention was paid to the diet, and insulin treatment was never given regularly.

#### 195. Goitre in the English School Child.

P. STOKES (*Quart. Journ. Med.*, January, 1928, p. 223) makes a critical analysis of the returns from the survey in 1924 of the incidence of thyroid enlargement among children aged 11 to 13. No reliable conclusions could be drawn directly from these statistics on account of the varying personal equations of the medical officers making returns. The first part of the paper deals with the computation of this factor by means of a sampling survey of 3,000 children made by the author in company with twenty of the observers con-

cerned. Study of the corrected returns shows that all degrees of thyroid enlargement are proportionately more frequent in goitrous than in non-goitrous districts, a finding which suggests that endemic goitre differs from "physiological goitre" merely in degree. Sex distribution is found to depend upon general prevalence; where this is low girls are affected five times as often as boys, while if the incidence in a district is high the sexes are affected equally. In regions where goitre is prevalent towns are less affected than rural districts, and coast towns generally are less affected than those inland. Incidence was found to be high principally in the West of England, and more especially in Cornwall, Devon, and Somerset, whence the belt of greatest prevalence passes northward into Northamptonshire, and Derbyshire, and up the Pennine Chale. Areas of moderate prevalence include Cheshire and Herefordshire and parts of North and South Wales. Geological formation is shown to influence goitre incidence, this being highest in country areas underlain by the trias, carboniferous limestone, and old red sandstone; evidence is submitted that this is the result of poor iodine content in these formations. In view of this probability it is thought that beneficial results might follow the administration of iodine to girls in those districts where goitre is most prevalent.

#### 196. Pre-scorbutic Myopathy and "Growing Pains."

C. FRIDERICHSEN (*Ugeskrift for Læger*, November 24th, 1927, p. 1069) gives evidence in support of his hypothesis that in early childhood pain in, and flabbiness of, certain muscles may be due to latent scurvy. In the records of two hospitals during the past fifteen years he has found 30 cases of infantile scurvy, in all of which, with only one exception, a rapid recovery was effected under an antiscorbutic diet. Though all these children suffered from pain in the limbs, and many of them from swelling of the limbs, there were only 16 in whom x-ray changes in the bones were demonstrable with certainty. In 4 cases there were doubtful changes and in 10 there were no changes in the bones demonstrable by the x rays. In 12 cases there was no bleeding from the gums, and in 11 no haemorrhages into the skin; haematuria was found in 19 cases. Only in 7 cases were periosteal changes detected. It was thus shown that in a large proportion of cases the x-ray examination of the bones and periosteum failed to explain why the pains were found in the limbs. In further support of his hypothesis that pain in the muscles occurs early in infantile scurvy, at a stage when other well-known signs have not yet developed, the author records the case of a child aged 3, admitted with the diagnosis of myelitis. After an attack of measles three months earlier he had lost his appetite and had become irritable. Pains in the muscles of the calf and thigh were regarded as growing pains. He began to limp and to develop flat-foot. Rickets was diagnosed, but antirachitic treatment proved ineffective. He became unable to stand or walk. The skin over the tender muscles was shiny and slightly oedematous, but showed no haemorrhages or bruises. The gums were slightly swollen, but did not bleed until pressed on with a spatula. Infantile scurvy being suspected an antiscorbutic diet, which included lemons, was prescribed, and after ten days the pain in the muscles had vanished, the child could walk, and his appearance had completely changed. The food at home had to be overcooked as the father's teeth were defective, and as the child never ate fruit or drank unboiled milk the attack of measles had evidently precipitated the scurvy.

#### 197. Four-hourly Breast-feeding.

MARGARET EMSLIE (*Arch. Dis. Child.*, October, 1927, p. 302) advocates that infants be breast-fed at four-hourly intervals—namely, at 8 a.m., 12 noon, 4 p.m., and 8 p.m. She thinks that these times interfere least with the many duties of a mother who has a baby, school children, and a husband to look after. The author stresses the importance of breast-feeding being made as easy as possible for a mother within the limits of a lactatory "zone of efficiency." Too often it is the intelligent, conscientious, and eager mother who becomes inhibited through overcrowding of her daily time-table, and has to fall back on supplementary feeds. A report is given of a series of 103 infants fed on this plan from early infancy, frequently from one month onwards, never later than from the sixth month. The transition from more frequent feeds to four feeds a day is now made in from four to six weeks. One breast only is used at each feed, which does not last more than twenty minutes. The average weight curve of the cases reported is slightly above and approximately parallel with the normal. Judged on the following points—a regular weekly gain of 6 to 8 oz., normal development, and comfort of mother and child—this method of feeding has, the author believes, been entirely satisfactory. A further series of ten cases is reported where, for reasons as a rule maternal, only three feeds a day were given—at 8 a.m., 1 p.m., and 6 p.m. The progress made by these children was also satisfactory.

## Obstetrics and Gynaecology.

## 193. Operation in two Stages for Large Ovarian Cysts.

THOUGH excision *en masse* of ovarian cysts without preliminary puncture constitutes the best procedure G. COTTE (*La Gynéc.*, November, 1927, p. 681) states that this is impossible in very large cysts. The danger of puncture lies in a too rapid and abrupt decompression of the abdomen, causing cardiac arrhythmia and intestinal paresis with abdominal distension, the latter being due neither to infection nor to peritonitis. The author excises the cyst a day or two after puncturing it, and advises that the puncture should be open to the surface rather than, as formerly, made blindly across the soft parts. He reports a case in which he incised the skin under novocain, punctured the cyst without opening the peritoneal cavity, and withdrew 10 litres of muco-purulent fluid; the abdominal wall was closed with three sutures. Next day the cyst (of the vegetating type without any signs of malignancy) was excised under spinal anaesthesia. Cotte insists upon the advantages of preliminary puncture and complementary appendicectomy in all cases of very large ovarian cysts.

## 199. Genito-peritoneal Tuberculosis following Abortion.

V. AZA (*La Med. Ibera*, October, 22nd, 1927, p. 338) reports the case of a married woman, aged 23, who began to menstruate regularly at the age of 12; she had had no children, but two miscarriages had occurred, the first, at four months, a year previously, being attributed to a fall, while the second had no apparent cause. She was emaciated and slender with pallor of skin and mucous membranes, and raised temperature and pulse rate; she presented symptoms suggesting an acute inflammatory process in the pelvic cellular tissue and uterine appendages. A blood count, however, showed a relative lymphocytosis suggesting a tuberculous affection. Anterior colpomy was performed and a large amount of foul faeculent material was evacuated. The patient's condition became gradually worse and death ensued. The necropsy revealed a stercoreal peritonitis in the left flank, with perforation of the ascending colon from three tuberculous ulcers. There was also generalized military tuberculosis of the peritoneum with the intestinal loops universally adherent.

## 200. The Use of Alcohol in Puerperal Sepsis.

J. BROCK (*Monats. f. Geburt. und Gynäk.*, August, 1927, p. 3) recommends uterine irrigation with alcohol as soon as symptoms of puerperal sepsis appear. He uses for this purpose about 1 litre of a table brandy containing about 40 per cent. of alcohol. He claims to have obtained very good results in this way, which he attributes partly to the local action of the alcohol and partly to its absorption into the system. Brock recalls Küstner's advocacy, in cases of puerperal sepsis, of alcohol given by the mouth in quantities sufficiently large to bring about a condition of deep intoxication at the time of the expected rigor; no bad results were noticed. It was suggested by Küstner that alcohol might produce its good effects by slowing the rate of metabolism and so conserving the strength of patients with lowered nutrition, but he believed rather that the inhibitory action of the alcohol on the bacteria was the prime factor.

## 201. Spinal Anaesthesia in Obstetrics.

S. A. COSGROVE (*Amer. Journ. Obstet. and Gynecol.*, December, 1927, p. 751); as the result of an experience of 54 cases, concludes that spinal anaesthesia has an important place in obstetrics, since theoretically it appears to be ideal for use in pre-eclamptic or eclamptic operative procedures. In practice he has found it free from danger, except in hypotension, the safe systolic minimum being 110 mm. Hg; it is suited for first-stage analgesia on account of its short duration. Working with a dosage of 50 mg. in the fourth lumbar interspace for vaginal and perineal operations and 75 mg. at the third interspace for laparotomies, he uses needles of small calibre, 22 to 20 gauge, dissolving weighed quantities of sterilized novocain crystals from sealed ampoules in 2 to 2½ c.cm. of spinal fluid, and injecting as slowly as possible with the patient on her side. At the end of the second stage there is entire soft-tissue relaxation which may obviate lacerations or the necessity for epiotomy. Its chief usefulness should be in conditions for which a general anaesthetic is contraindicated, and it appears to be directly conservative of both maternal and foetal life. Cosgrove claims that in obstetric laparotomies it has the same advantages as in general surgery, giving complete anaesthesia and muscular and visceral relaxation, with relatively slight bleeding, minimal post-operative discomfort, and a smooth convalescence. For operative procedures in pregnancy toxæmia and eclampsia this method is especially indicated.

## Pathology.

## 202. Laboratory Diagnosis of Small-pox Virus.

R. D. DEFRIES and N. E. MCKINNON (*Amer. Journ. of Hygiene*, January, 1928, p. 107) have devised a laboratory test for the recognition of small-pox virus. Hitherto use has been made of the allergic reaction observed in the skin of a rabbit previously immunized with vaccinia virus and the corneal reaction which follows the application of small-pox virus to the eye of a normal rabbit. The authors find neither of these tests to be reliable. The former reaction is so variable, both in occurrence and character, that accurate interpretation is often impossible; the latter reaction occurs in only about 50 per cent. of cases. They now draw attention to the reaction that follows the intradermal injection of small-pox material into the normal rabbit. In the course of fifty injections they obtained a definite reaction each time. A red palpable lesion, varying from about 10 to 20 mm. in diameter, appears on the first or second day, and reaches its maximum development about the fourth day, when it resembles a firm elevated plateau; subsequently the central redness gives place to a straw colour, and desquamation or crust formation often occurs; the lesion disappears by the twelfth day and leaves no scar. Chicken-pox material gives no skin reaction in the normal rabbit. For laboratory diagnosis the authors recommend that the suspected material should be inoculated intradermally into normal rabbits and into vaccinated rabbits; a typical lesion in the normal contrasted with a modified lesion in the vaccinated animals is diagnostic of small-pox.

## 203. Experimental Culture of Endometrium.

P. CAFFIER (*Zentralbl. f. Gynäk.*, January 7th, 1928, p. 63) has tried to cultivate fragments of human endometrium *in vitro*. Using human or animal plasma as a medium, to which in some cases ovarian or other organ extracts had been added, he found that in many cases a villi-like membrane grew out from an implanted endometrial fragment, whatever its cyclical phase. Decidual tissue up to, but not beyond, the third month of pregnancy gave similar results, but no growth occurred in the case of spontaneously discharged menstrual fragments. These experiments, like those of Helia, were inconclusive as a test of the validity of Sampson's theory of production of "endometrioma," for microscopical examination of the villi-like outgrowths failed to show whether the cells which they contained originated from epithelial cells or from stroma cells, which in the endometrium are known to possess special characters.

## 204. The Function of Cholesterolin.

As illustrating various properties of cholesterolin, GUGEROT (*Paris Méd.*, January 21st, 1928, p. 64) reports a case of tuberculides which was apparently cured by a subsequent attack of xanthoma. Following two attacks of sero-fibrinous pleurisy those tuberculides appeared in a young man with latent tuberculosis, and persisted without any change for about ten months. At this date xanthomatous deposits commenced to infiltrate the tuberculides, and were confirmed by histological and chemical examination. The xanthoma slowly increased in size, at the same time the tuberculous lesions gradually regressed. Finally, five years later, both conditions cleared up, only a slightly red, fibro-elastical atrophy persisting. The patient had no antecedents of hereditary or acquired syphilis, and repeated Wassermann tests were negative. During the xanthomatous period he developed signs of aortic insufficiency, and, as he presented no cardiac lesions when first seen, Gugerot attributes this to aortic xanthoma. Gugerot adds that xanthomata are characterized by the presence in the skin of masses of large lymphoid connective tissue cells with a reticular vacuolated protoplasm. These vacuoles contain the ethereal salts of cholesterolin or lipids, and those of glycerin or neutral fats. The author maintains that xanthoma is a hypercholesterinaemia, and fixes the cholesterolin in the tissues, especially the skin, just as gout fixes uric acid in the form of tophi. The process is an active, not a passive, one, and is therefore a defensive reaction. Many workers have demonstrated that the lipoids, of which cholesterolin is the type, possess antibaemolytic, antitoxic, and bacteriolytic powers. Gorard and Lemoine have stated that the amount of blood cholesterolin is below normal in tuberculosis, and that the low resistance noted in this disease is due to a lack of cholesterolin reserve. They insist on the auto-protection conferred by the lipoids in tuberculosis, and advise the treatment of this infection by biliary lipoids. Gugerot believes that the appearance of xanthoma in tuberculosis is a favourable sign, and that an endeavour should be made to create such a condition by a suitable diet, with the ingestion and injection of cholesterolin and other lipoids. Care should be taken in pursuing this treatment, as in many cases the action of cholesterolin may become injurious if the substance is present in excessive amounts.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 205. Active Immunization against Scarlet Fever.

D. VAN DORP-BEUCKER-ANDRIJAE and N. SPEELMAN (*Nederl. Tijdschr. v. Geneesk.*, December 24th, 1927, p. 2692) record their observations on 233 persons who were actively immunized against scarlet fever at the Marine Hospital at Katwijk. No severe reactions were seen except in a nurse, who had a high temperature and nausea for a few days after the first injection. Three injections were given, with a week between each, the doses being as follows: Up to 6 years of age inclusive, 200, 300, and 400 skin test doses; for children aged from 6 to 12 years, 300, 450, and 950 skin test doses; and for persons over 12 years, 400, 600, and 1,200 skin test doses. The authors find the Dick test less reliable than might be expected. A reaction which is at first negative may become positive because the first test was not performed properly, or it may happen that after an attack of scarlet fever or active immunization the reaction slowly becomes positive again. It is probable that in a large number of these cases which become negative again the immunity is only lost in the body fluids, it having been converted into a latent cellular immunity; there is thus no longer any free antitoxin present in the body fluids, but a small quantity of toxin is sufficient to stimulate the allergic cells to the rapid production of antitoxin, so that the Dick reaction becomes negative again.

216. L. S. L. MEYER (*Nederl. Tijdschr. v. Geneesk.*, January 7th, 1928, p. 25) records the results of active immunization against scarlet fever among the school children at Velsen in Holland. The Dick test was performed on 3,159 out of a population of 6,234 school children, with the following results. In 835 the reaction was negative, in 1,903 positive, and in 420 doubtful—a proportion of 27, 60, and 13 per cent. respectively. There was little difference in the results in boys and girls. Of 39 children who had previously had scarlet fever 27 gave a negative, 6 a positive, and 6 a doubtful reaction. The test was also performed on 63 children in whose families there had been a case of scarlet fever, the results being as follows: positive 25 cases (45 per cent.), negative 17 cases (31 per cent.), and doubtful 13 cases (24 per cent.). All the children with a positive reaction were inoculated, 3 injections being given of 3/4 c.c.m., 3/4 c.c.m., and 1 c.c.m. respectively. The result of control examinations which were carried out in 453 children three to four months after the inoculation was disappointing. Whereas on control examination after active immunization against diphtheria all the inoculated children gave a positive Dick reaction, many gave a negative reaction, the rest were negative. The success was thus not so great in scarlet fever as it was suggested that a larger quantity of scarlatinal toxin should be inoculated.

217. W. W. MURPHY (*Arch. of Ped.*, November, 1927, p. 727) performed the Dick test in 404 school children, of whom 304 (75 per cent.) were positive and 100 were negative. Of the 304 susceptible children who were inoculated with scarlatinal toxin 232 (76 per cent.) became Dick-negative, 31 (10 per cent.) remained positive, and 41 (13 per cent.) were lost sight of. There were thus 232, or about 17 per cent., immune to scarlet fever out of a total school population of 1,927. The reaction to the injection of toxin was moderately severe, consisting of marked local swelling, redness, tenderness, and pain, accompanied by a temperature of 103° to 105°, violent headache, vertigo, vomiting, and prostration. All the patients who had systemic symptoms showed a mild scarlatinal rash followed by slight desquamation. In no case was there any permanent or serious result. The dosage consisted of 500, 1,500, 5,000, 15,000, and 20,000 skin test doses. No definite relation was found between different age groups and either susceptibility to scarlet fever or the degree of active immunity obtainable.

### 208. Angina Pectoris.

K. F. WENCKEBACH (*Wien. klin. Woch.*, January 5th, 1928, p. 1) draws attention to various points in the symptomatology of angina pectoris which are not adequately explained by the prevailing theories of its pathology. Though in ambulatory cases the attack may be induced by quite slight exertion, more vigorous exercise may merely produce dyspnoea without pain; moreover, though the patient may have to stop several times when he first goes out, after a while he can continue walking without discomfort. Wenckebach considers

that the symptoms of angina are closely related physiologically to the distress experienced by normal persons during severe exercise (especially running and rowing) before they get their "second wind." The physiological process is explained by an increased supply of blood from the viscera to the heart and larger arteries, an acceleration of the pulse rate producing a rise in blood pressure, and congestion in the aorta before this head of pressure finds relief in the dilatation of peripheral arteries and veins. In the anginal attack of the ambulatory type (the status anginosus differs in many respects) the "second wind" stage is not reached, though the dilatation produced by nitrites is said to be somewhat analogous. Wenckebach believes that, just as the pain in Raynaud's disease occurs as the circulation is restored, and the femoral artery is often very tender to pressure just below Poupart's ligament during an attack of intermittent claudication, so the pain of an anginal attack is due not to ischaemia of the peripheral, but to distension of the proximal, parts of diseased coronary arteries, which are somehow more sensitive to alteration in tension. Since the coronary arteries are developed from the proximal section of the aorta their motor and sensory innervations are the same; therefore either or both together can produce the typical anginal syndrome, and there is no need to attempt to distinguish aortic from coronary angina. Contraction of vessels at any part of the periphery, or several parts simultaneously, may initiate an anginal attack by increasing the pressure in the aorta and coronary vessels, and may be relieved or prevented by such medicaments as nitrites, which produce peripheral dilatation. It follows from this that when the left side of the heart fails there will be insufficient pressure to produce the necessary tension, and the painful anginal attacks will often diminish as the signs of heart failure increase. It has been observed also that digitalis, by restoring the powers of the heart, may produce a recurrence of anginal attacks, which had temporarily ceased. Wenckebach disputes the originator's explanation of the rationale of Jonnesco's sympathectomy (and Lericho's operation on the femoral artery) on anatomical grounds, and considers that the beneficial effects are due to interruption of afferent sensory paths, whereby a break is made in a vicious circle of pain and raised pressure.

### 209. Encephalitis in Measles.

J. BOISSERIE-LACROIX and J. MALAPLATE (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, December 25th, 1927, p. 946), who record an illustrative case, remark that, apart from convulsions at the onset, nervous complications in measles are very rare. The age at which they are most frequently observed is from 2 to 7, but Bourne has reported a case in an infant of 14 months, and Dienlaffoy, Lagare, and Lemièrre have seen cases in adults. It is chiefly in severe attacks of the haemorrhagic form that nervous complications occur; they are frequently accompanied by pulmonary congestions or broncho-pneumonia, and may develop in the eruptive stage or later in convalescence. The present case is said to be the first example on record of meningo-encephalitis occurring during the period of invasion. The authors adopt the following classification of the nervous complications of measles. (1) The upper or cerebral form, which chiefly occurs in severe measles and is characterized by stupor, coma, and convulsions, which are bilateral or predominant on one side of the body. (2) The intermediate form, in which there is a predominance of ocular disturbance, ataxia, and bulbo-pontine symptoms. (3) The low or spinal form. A mental and meningeal form may also be described. The encephalitis of measles in cases which have come to necropsy does not differ from acute encephalitis due to other causes.

### 210. Paratyphoid C Fever.

A. N. KINGSBURY, J. A. LESSLAR, and M. KANDICH (*Malayan Med. Journ.*, December, 1927, p. 127), who record two illustrative cases, state that in paratyphoid C fever the onset is usually sudden; the duration depends on the severity of the infection and the degree of involvement of the respiratory system. Bronchitis and patches of broncho-pneumonia are not uncommon, and the causal organism may sometimes be isolated from the sputum. The course does not exceed five to six days in mild cases, and since the mortality rate is low, few descriptions of post-mortem findings have been published. Usually some congestion of the upper part of the small intestine has been noted as well as congestion, and small superficial erosions of the mucous membrane of the colon. The authors' first case occurred in a Chinese male, in whom the only symptoms were fever, loose stools, and an icteric

tint of the skin; death followed a twelve days' illness. At the necropsy no abnormality of the heart, lungs, or kidneys was noted. The spleen was enlarged and the liver congested, but no ulceration or inflammation was noted in the intestinal canal. The serum failed to agglutinate ommisions of *B. typhosus* or of the paratyphoids B and C, but it agglutinated the paratyphoid C strain to a titre of 1 in 6,400. The second case occurred in a Tamil woman, aged 26, who had a remittent fever for twelve days, which was not affected by quinine, although malignant tertian parasites were found in the blood. *B. paratyphosus* C was isolated from the urine and was agglutinated by the specific serum in high dilutions. Owing to the concurrent malarial infection the characteristic slow pulse of enteric fever was not present. Subcutaneous inoculation of the strain into a guinea-pig caused death in thirty hours, and the necropsy showed extensive subcutaneous haemorrhage, splenic enlargement, and a blood-stained peritoneal exudate. The bacillus was recovered from the heart, blood, spleen, and peritoneal fluid in pure culture.

#### 211. Tularaemia.

L. J. MERRIMAN (*Minnesota Med.*, December, 1927, p. 719), who records four cases originating in Minnesota, remarks that tularaemia, which in nature occurs in wild rats, ground squirrels, and wild rabbits, may be transmitted to man by (1) handling diseased animals; (2) contamination of the hands or conjunctiva with the tissues or body fluids of diseased animals; (3) the bite of diseased animals; (4) contamination of the hands or bites of flies, ticks, bed-bugs, or lice which have bitten diseased animals; (5) the bite of any animal that has eaten diseased rodents. The causal organism, *B. tularensis*, can penetrate the unbroken skin or conjunctiva, but a frequent portal of entry is a wound. Laboratory workers are very prone to contract the disease. The organism is Gram-negative, non-motile, and non-spore-bearing; it occurs in both bacillary and coccoidal forms, and appears early in the blood of the lower animals as well as in man. It grows well on coagulated egg yolk and blood glucose, and on cystine agar, but not on ordinary media. Four types of the disease are described: the ulcero-glandular, oculo-glandular, glandular, and typhoidal. The period of disability is rarely less than a month. The mortality is not high, but occasionally a fatal case occurs. Tularaemia must be distinguished from typhoid fever, septicaemia, tuberculosis, and Malta fever. The following points are of diagnostic value: a history of contact with rabbits or rodents or of bites; a primary papule or wound; persistent local glandular enlargement; fever of two to four weeks' duration; a negative Widal reaction; and a relatively low leucocyte count. The diagnosis is proved by agglutination of *B. tularensis* with the patient's serum. The treatment is entirely symptomatic.

#### 212. The Heart in Fungus Poisoning.

A. S. HYMAN (*Bull. Johns Hopkins Hosp.*, January, 1928, p. 8) describes an investigation of the cardio-vascular disturbances in a case of mushroom (*Amantia phalloides*) poisoning. This fungus was consumed in error by a party of four persons, three of whom recovered completely after gastric lavage. The fourth patient complained of severe headache and giddiness, and ten hours after the ingestion of the poison there was observed some irregularity of the pulse, which became more marked on the following day. Two days after the onset all symptoms except weakness had disappeared, while examination showed the rhythm of the heart to be mainly regular with frequent irregularities. There was no loss of conductivity to the radial pulse; apart from a soft systolic murmur at the apex and a trace of albumin in the urine no further signs of disease were found. Electro-cardiograms taken at this time showed delay in conduction of the normal stimulus through the heart, the P-R interval being slightly prolonged, and the QRS complex split and grossly delayed. Diphasic T-waves in conjunction with the above signs led to a diagnosis of right bundle-branch block, while the electrical record further showed the irregularity to be due to right ventricular extra-systoles. Eighteen days after the onset the electro-cardiogram showed improvement in the condition of the heart, but there were still signs of severe myocardial damage. Four months from the beginning of the illness a third examination was made, this showing almost unimpaired conduction, while five months later the electro-cardiogram was normal. The author reviews the literature on the pathology of mushroom (muscarine) poisoning, the changes generally found being fatty or lipid degeneration of the myocardium, sometimes with fragmentation. In the case described such damage probably occurred in the neighbourhood of the anterior papillary muscle of the right ventricle, the close anatomical relation of this region to the right branch of the bundle of His explaining the abnormalities found in the electrical changes of the heart.

## Surgery.

### 213. Primary Carcinoma of the Ureter.

F. VOLANTE (*Arch. Ital. di Urol.*, December, 1927, p. 105) has collected and discusses 38 cases, including a personal one in a man aged 49, of primary carcinoma of the ureter, the first of which was reported by Wising and Blin in 1878. Volante comes to the following conclusions: (1) The ureter may be the primary site of various malignant epithelial tumours. (2) Not all the recorded cases are to be regarded as genuine primary tumours of the ureter; the large number of organs affected and the development of the tumour in persons who had already been operated on for tumours elsewhere throw a doubt on the diagnosis. (3) Papillary carcinomata are by far the most frequent, and are usually to be regarded as the malignant transformation of benign papillomata. (4) Lithiasis has been regarded as responsible for the condition, and has actually been found in a certain number of cases, the chronic irritation produced by the concretion and the concomitant irritation being an explanation of the origin of the tumour. (5) Leucoplakia and the cell nests of von Brunn, both of which are the result of chronic inflammation, are of considerable importance in the pathogenesis of epithelial tumours of the ureter. (6) Embryonic malformations and trauma are also of importance in the pathogenesis. (7) The site of predilection for the tumour is immediately below the normally constricted parts of the ureter. (8) The tumour may develop concentrically or eccentrically, or both forms may be combined. (9) Hydronephrosis is the most frequent result and often the first obvious sign of ureteral tumour; other symptoms which are inconstant are haematuria and pain. The latter is most frequent in the papillomatous growths. (10) The presence of tumour elements in the urine is a good diagnostic sign, but is rarely found.

### 214. Tuberculosis of the Breast.

V. ALOI (*Rif. med.*, January 9th, 1928, p. 33), who records an illustrative case, remarks that tuberculosis of the breast is a rare condition, of which only 200 cases have hitherto been reported in women and 11 in men. The earliest cases in which the diagnosis was based on the naked-eye appearances were reported by Cooper (1829), Nélaton, Velpeau, and Billroth. Dubar, in 1881, was the first to describe the morbid anatomy, and the following year Olmacker demonstrated the etiology experimentally. It is probable that many cases have been mistaken for cancer of the breast. Very few cases have developed during lactation (Häbermass, Piskacek, and Plujette). Aloï's case was in a woman, aged 27, who had noticed a swelling on the outer side of her right breast three years previously during the sixth month of lactation. Since then it had gradually increased in size. The Pirquet reaction was positive, and x-ray examination showed caries of the sixth rib. The upper and outer quadrant of the breast was removed, leaving the nipple and areola. Complete recovery followed. Examination of the excised tissue showed numerous cavities filled with caseous tissue, giant cells, and a few tubercle bacilli.

### 215. Treatment of Fistula in Ano.

LOP (*Bull. Soc. de Théor.*, December 14th, 1927, p. 276) states that he is now less inclined than formerly to operate on fistula in ano. It often happens that a primary localization of tuberculosis may simulate an ordinary acute abscess of the margin of the anus, giving rise to violent pain, interference with defaecation, and a high temperature; in such cases an operation is inevitable. In at least six-tenths of the patients a blind external or complete fistula communicating with the rectum is left, and in such cases Lop considers it advisable not to interfere, even when clinical examination, radiocopy, and laboratory tests show that the lungs are normal. He has found that a localization of anal tuberculosis due to passage through the bowel of infected broncho-pulmonary secretion is much less frequent than a primary localization, if, indeed, it really exists. Lop therefore only operates on cases of anal fistula after carefully examining the lungs and sputum, and investigating the discharge from the wound for the tubercle bacillus. He refuses to operate whenever the bacillus is found in the discharge, even when it is absent in the sputum and nothing abnormal is found in the lungs, nor does he operate on any individual in good health in whom the fistula has been in existence for some time and has not been painful. He has recently seen ten cases in which a radical operation was successfully performed; six of the patients subsequently died of pulmonary tuberculosis. Abstinence from operation applies only to the so-called spontaneous fistulae, since it is required for those which result from trauma of any kind.

**216. Post-operative Complications of Appendicitis.**

According to C. W. CUTLER, jun. (*Amer. Journ. Surg.*, December, 1927, p. 602), success or failure in the treatment of suppurative appendicitis depends largely on the post-operative events. In a series of 394 cases 41 patients died, giving a mortality of 10.5 per cent. It becomes apparent that in the vast majority of cases prostration is more dangerous than operation. Peritonitis was the most serious complication, and in these cases the injection of saline solutions and morphine with the Fowler position was the chief line of treatment. Gastric lavage and plintrin were also employed. High enterostomy was performed for paralytic ileus in five cases, and one patient recovered. Cutler insists that enterostomy to be of any use must be performed early. Secondary abscess was also a serious complication in 18 cases; 5 patients died, including 2 with subphrenic abscesses. In these cases drainage was employed as soon as the abscess had become localized. There were 5 cases of faecal fistula and 2 required further operation to close them. To prevent this Cutler advises that the drains should be moved daily. Mechanical ileus occurred in 5 cases and necessitated operation. Post-operative hernia was found in 6 cases (1.5 per cent.); to prevent this the wearing of a belt is advised for six months after operation. Pulmonary complications were not frequent, but one patient died from embolism on the fifth day.

**217. Recurrence after Operation for Carcinoma of the Breast.**

E. DAHL-YVERSEN (*Lyon Chir.*, November-December, 1927, p. 648) refers to the numerous attempts to determine the frequency of recurrence of carcinoma of the breast after operation, and adds that the relation between the histological appearances of the growth and the prognosis after operation has not been settled. Statistics show that after the radical operation 45 per cent. of the patients remain for three years without sign of recurrence. In a series of 126 cases he finds that 33 per cent. showed no sign of reappearance of the condition at the end of three years. He concludes that a point on which a prognosis can be given is the size of the tumour; when this was small, the size of a plum, only 17 per cent. showed recurrence, but in large growths, the size of an egg, 87 per cent. showed recurrence within three years. Cases of medullary carcinoma all recurred within this period, as did 57 per cent. of cases of scirrhus. When the axillary glands were involved there was recurrence in 80 per cent., but if the glands were not affected only in 41 per cent. within three years. Involvement of these glands was found in 65 per cent. of the cases. The clavicular glands appear to be affected in 27 per cent. of cases. As experience shows that the clavicular glands may be affected, even when the axillary glands are clear, they should, according to the author, be removed in all cases.

**218. Osteomyelitis of the Os Pubis after Measles.**

RAESCHKE (*Klin. Woch.*, January 8th, 1928, p. 72) describes the case of a boy, aged 7, who suffered from measles four weeks previously. After the rash had disappeared the fever still remained, and the patient did not improve. Suddenly the temperature rose still higher and severe pain was felt in the left inguinal region, so that the leg could not be moved; a puncture later removed some serous fluid, which was sterile. About a week afterwards the hip-joint was free from pain, but the perineum became swollen; after removal of the swelling by poultices a hard painful infiltration remained on the ascending ramus of the pubis, and an x-ray examination showed distinct periosteal thickening. The infiltration increased in size and became soft; sterile fluid was removed by puncture. Another x-ray examination showed softening of nearly the whole of the ascending ramus of the pubis. On operation a cavity the size of a walnut was found; its contents were removed and the cavity was drained. Recovery was uneventful.

**219. Separation of Lower Femoral Epiphysis.**

A. S. GRISWOLD (*Journ. of Bone and Joint Surg.*, January, 1928, p. 75) records a case of separation of the lower femoral epiphysis—not a very common type of femoral fracture, but often associated with nerve or vessel injury. It frequently leaves the knee-joint with considerable impairment of function. Acute flexion has usually been adopted in the treatment of those cases, and plaster-of-Paris has been used to maintain this position. Griswold's case occurred in a boy aged 8. The fracture was reduced under anaesthesia, and acute flexion was maintained for the first day. Each day the knee was moved through a few degrees and extension increased. Twenty-six days later complete extension was possible and the child could walk with a stick. At the end of one year it was impossible to tell which leg had been injured.

**Therapeutics.****220. Treatment of Small-pox by Red Light.**

J. H. THIERRY (*Ugeskrift for Læger*, January 12th, 1928, p. 29) refers to Niels Finsen's earliest work on the action of light on the human body, in which he suggested that suppuration in small-pox vesicles was caused by the action of the light rays of the sun on the skin. If such rays could be excluded before suppuration had begun it could be prevented, the danger of death from suppuration fever would be eliminated, and disfiguring scars avoided. Thierry remarks that in Denmark there has been but little opportunity to test the accuracy of this theory, the small epidemic in 1894, during which a "red ward" was provided for some cases, yielding insufficient evidence. In the Hôpital del Salvador in Valparaiso, in the beginning of 1921, he was able to obtain a 16-bed pavilion with only red light. The one doorway was provided with three doors, only one of which could be opened at a time, and the double windows provided with red glass were screwed fast so that they could not be opened. Ventilation and light were supplied by three petroleum lamps protected with red glass, having chimneys which passed up through the roof; holes in the floor were connected with bent tubes through which plenty of air, but no light, could pass. The lamps were kept burning day and night, and the ventilation they provided was as effective as that of the pavilions with open floors and windows. The completeness with which daylight was excluded may be gauged from the fact that photographic paper exposed in the pavilion for three months was scarcely discoloured. Only patients in the first stage of the disease were admitted to this pavilion, and none in whom pustules had already formed. While the death rate was 41.66 per cent. (192 patients, 80 deaths) among these "red-light" patients, it was 41.96 per cent. (1,582 patients, 664 deaths) among all the patients admitted to hospital. It should be noted that the 23 patients who died in the primary stage of the disease were in the red room. When these cases were subtracted, as well as those in which haemorrhages into the vesicles obscured the diagnosis of suppuration, there remained 159 "red-light" patients, of whom only 9, or 5.66 per cent., showed no suppuration. There were 40 who suffered from very severe suppuration and scarring. Though exact data were not available as to the proportion of patients who were treated in daylight, and whose vesicles did not suppurate, the author thinks that the percentage of "daylight" patients free from suppuration was no less than that of the "red-light" patients. But although the death rate, and the frequency and severity of suppuration and scarring seemed to be uninfluenced by red light, it evidently had a beneficial effect so far as the eyes were concerned, for, with only one exception, the "red-light" patients were free from any serious complaints of the eyes, while about 10 per cent. of the "daylight" patients developed pustules of the cornea, about 3 per cent. losing one eye, and about 1 per cent. both eyes. With regard to the frequency of haemorrhagic cases, and of abscesses in or under the skin, no distinctions could be drawn between the "red-light" and the "daylight" patients.

**221. Late Treatment of Infantile Paralysis.**

E. DELCROIX (*Bruxelles-Médical*, January 15th, 1928, p. 360) describes his method of dealing with limbs affected by infantile paralysis. Hitherto the treatment of poliomyelitis at the stage when the paralyses are determined has chiefly consisted in endeavouring to correct muscular weakness and deformities. Attention is now being directed primarily towards the nutrition of the affected part. Delcroix bathes the paralysed limbs in warm sea-water irradiated by ultra-violet rays; the name he gives to this type of bath is "actinotmarine." It is found that the combined action of the thermic element and the variations in the difference of potential in the osmotic exchanges increases the nutrition of the tissues. Encouraging results had previously been obtained from hot sea-water baths. Sea-water, containing as it does a large number of electrolytes, constitutes a highly ionized medium, and when it is reinforced by ultra-violet radiation the results have been very promising. The study of the oscillographic index, which is the visible expression of the total pulse of a limb, gives a direct indication of the peripheral circulation. In order to gauge the possible variations of this index the same children were submitted to the following tests: (1) warm water bath, (2) irradiated warm water, (3) warm sea-water, and (4) irradiated warm sea-water. The other factors of the different tests were identical in all. When the rate of circulation after each test was observed it was found that the maximum oscillatory amplitude occurred after the fourth test, the actinotmarine bath. Delcroix reports eleven cases in which the attack of poliomyelitis preceded the initial treatment at periods ranging from six weeks to nine years. All except two of these patients had been submitted to the

usual therapeutic procedures without success. Before complete recovery was obtained the number of treatments needed varied, but in the series quoted the previously paralysed child was able, after twelve to twenty-four baths, to stand alone, to walk, and to ascend and to descend stairs. The results have been constant and were maintained. The patients treated in 1926 were seen in 1927, and were found to be as well as, and in some cases better than, at the end of the course. Delcroix adds that this method synthesizes two important elements in therapeutics—the electric and the thermic; to the judicious association of these two are attributed the encouraging results which have been obtained.

## 222. Treatment of Syphilitic Cardio-vascular Diseases.

A. SÉZARY (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, December 1st, 1927, p. 1547) agrees that antisyphilitic treatment should be modified in the case of patients suffering from any grave cardiac, hepatic, or renal complications which are not of syphilitic origin. Advancing age is not a contraindication to the use of the arsenobenzols, but only necessitates their careful administration. He doubts whether there is any real danger of aggravating the arterial hypertension in the case of aged syphilitic patients by specific medicaments, even when the hypertension is non-syphilitic, and thinks that the treatment of cases of cardiac syphilis, as of syphilitic skin diseases, should be governed by the individual circumstances. In ordinary cases bismuth and mercury are most often employed, but neosalvarsan remains the most powerful agent, and occasionally mixed arsenical and bismuth treatment is indicated. Patients under the age of 50 bear the treatment better and the clinical diagnosis of cardio-vascular syphilis is easier in such cases, since atheroma and arteriosclerosis are seldom present. Syphilis may play an important part in cardio-vascular disease in much older patients; a gyna pectoris and aortitis may yield to antisyphilitic treatment even though the clinical diagnosis of syphilis is not fully established. Such treatment should be neither brief nor insufficient, and arsenic, bismuth, or mercury should be used, as indicated clinically. Unsatisfactory results may be due to the presence of atheroma or to degeneration of the tissues. Three cases of aortic aneurysm treated with bismuth are reported. One patient was relieved, and skiagrams showed that the aneurysm had not increased in size. In the two other cases, however, the symptoms became worse, and in one of these, in spite of three courses of bismuth, the aneurysm increased to double its size in a few months. The results of specific treatment of angina pectoris are, however, so encouraging that it should be given in all cases where syphilis is suspected. Sézary quotes seven cases, in four of which the results were very good. One man, aged 61, contracted syphilis when 23; the slightest exertion caused an anginal attack. He was treated with bismuth for two years; the attacks gradually decreased and finally disappeared, and the patient was able to lead an active life. In three other cases, however, the patients were not relieved. The average age of those who were relieved was 56.5 years, while that of those who were not relieved was 51 years. Of the former two were treated with novarsenobenzol and two with bismuth; of the latter, one was treated with novarsenobenzol and the other two with bismuth. In aortitis the disappearance of bruits cannot be expected, but symptomatic improvement may follow specific treatment although the Wassermann reaction remains positive. Of twelve cases of aortitis five were greatly benefited. Sézary believes it possible to cure completely syphilitic cerebral arteritis, and advises that intensive treatment should be started immediately in all cases of hemiplegia in young subjects, unless contraindicated by grave visceral disease.

## 223.

### The Amino Bases of Ergot.

RAYMOND-HAMET (*Presse Méd.*, January 11th, 1928, p. 35) describes three amino bases of ergot, tyramine, histamine, and acetylcholine, and discusses the action of each on the uterus, circulation, heart, respiration, intestine, and sympathetic system. In a short note he states that the four alkaloids of ergot—ergotinine, ergotaminine, ergotamine, and hydro-ergotinine—possess a long, excitant uterine action, a profound vaso-constrictive effect, and a sympatholytic action, and that the last two are markedly powerful agents. The amino bases are present merely in minute quantities in fresh ergot, and are appreciable only after decomposition; when required, therefore, they should be prepared synthetically, since ergot is not administered for the effect produced by the amino bases. They have the same action on the uterus as the alkaloids, but this is very transitory, and even in therapeutic doses they possess highly injurious properties. The bases are devoid of all sympatholytic power, and the action of tyramine is partly explained by its stimulation of the sympathetic nervous system. This base is a vaso-constrictor, but histamine and acetylcholine are so power-

fully vaso-dilatative and hypotensive that their action is first manifested when injected with tyramine or even with the alkaloids. It has been shown both chemically and physiologically that the galeic preparations of ergot contain little or none of the alkaloids, but are rich in the amino bases. Hence they almost always produce vaso-dilatation and hypotension, and their use is contraindicated, vaso-constriction being the desired end for which ergot is administered.

## 224.

### Treatment of Erysipelas.

E. S. PLATOU, F. W. SCHLUTZ, and L. COLLINS (*Amer. Journ. Dis. Child.*, December, 1927, p. 1030) report a series of 155 cases of erysipelas, of which 80 were treated with x-ray irradiation, 30 with the antitoxin, and 35 with magnesium and glycerin packs. The return to normal temperature averaged 1.5, 2.2, and 3.4 days respectively in the three groups, while the subsidence of symptoms such as pain, toxæmia, and general malaise took 2, 3.8, and 8 days. The mortality was 6, 6, and 23 per cent. respectively. Extension of the disease occurred in 21, 46, and 68 per cent. of the cases in the three groups. In a further series of ten especially grave cases a combination of x-ray and antitoxin treatment was particularly successful, the erysipelas disappearing invariably, though one infant aged 3 months developed broncho-pneumonia and meningitis later and died.

## Ophthalmology.

## 225.

### Palpebral Cysts.

A. GABRIÉLIDÈS (*Ann. d'oculistique*, December, 1927, p. 926) states that what were described as hydatid cysts of the eyelids by the early Greek writers, such as Galen and Paulus Aegineta, were cysts with watery contents formed behind the suspensory ligament of the tarsus and below the anterior extremity of Tenon's capsule. These cysts occur both in children and in adults. Gabriélidès distinguished them from chalazions for the following reasons. (1) A chalazion is not contained in a membranous sac which can be seized by the fingers and extirpated. (2) A chalazion does not contain a clear fluid, but an amorphous material. (3) A chalazion is not situated at the upper part of the lid below the eyebrow, but on the tarsus itself. (4) A chalazion does not possess deep roots. The hydatid cysts of the lids described by the ancient Greeks are really the only cysts of modern ophthalmologists. They may be congenital like dermoids, occur in early life, and gradually increase in size so as to interfere with vision. They contain a fluid, which is either clear like glycerin or yellowish like ascitic fluid; and fats (stearates, glyceroleates, and palmitates). Treatment consists in their total extirpation or in removal of the most prominent part, followed by scraping out the bottom of the cyst. Gabriélidès describes five personal cases in patients aged from 49 to 60.

## 226. Detachment of the Anterior Layers of the Iris.

M. J. SCHOENBERG (*Arch. of Ophthalmol.*, November, 1927, p. 538) describes a case of this condition. The patient had lost his right eye from iridocyclitis many years previously. He was a high diver at a circus, and on one occasion, after his dive, as he came to the surface of the water, he found that he had become blind. After a week, however, his vision had returned to normal; for some time previous to the accident, however, it had not been good, and he presented himself at hospital on this account. On examination he was found to have advanced chronic glaucoma in the left eye; the cornea, pupil, and media were clear, but the optic disc was atrophic and deeply cupped. The anterior layers of the iris were stripped off and were floating as threads in the anterior chamber. There were cracks in the deeper layers and in the pigment layer. The sphincter papillae was intact and the angle of the chamber was not obviously obstructed. The most probable explanation was that the force of the high dive had driven the aqueous into the iris tissue, tearing the strands apart. The author adds that cases of a similar nature have been described, but in very old people and without a traumatic history.

## 227.

### Ocular Pemphigus.

G. M. CONSTANS (*Amer. Journ. of Ophthalmol.*, November, 1927, p. 810) describes three cases of ocular pemphigus and discusses this rare disease, which may occur in the eyes alone or associated with generalized skin pemphigus. The etiology is quite unknown; it has been attributed to toxic action upon the nerve centres. The condition in the eye starts with swelling and congestion of the conjunctiva and the formation of bullae which rupture. Later shrinking of the conjunctiva with the formation of adhesions occurs—the condition is sometimes called "essential shrinking of the conjunctiva"—

and, subsequently, the cornea becomes dry, dull, and atrophic. Treatment consists in removing all causes of sepsis, and keeping the eye as clean and moist as possible, repeated boric acid irrigations, a mild conjunctival antiseptic, such as zinc sulphate 1/4 grain to the ounce or 1 per cent. mercuriochrome, and the instillation of liquid paraffin at frequent intervals. Prognosis is ultimately bad.

#### 228. Sarcoma of the Uveal Tract.

R. C. DAVENPORT (*Brit. Journ. of Ophthalmol.*, December, 1927, p. 603) reviews all cases (35 in number) of sarcoma of the choroid seen at Moorfields Eye Hospital during the period 1918-23, the average being 7 a year. Previous records of past series (1871-1925) show almost exactly the same yearly occurrence. Davenport thinks the case incidence at Moorfields nowadays is about 2 in 10,000. He has been able to trace 22 patients out of the 35; of these, 10 are known to be alive and well. Out of the whole series 28.5 per cent. are known to have lived free from recurrence for more than three years after excision. Twelve patients (34.28 per cent. of the whole series) are known to have died, and 7 of these (20 per cent. of the whole series) died from recurrence of the sarcoma. Of the untraced cases, two were seen alive three years after operation.

## Obstetrics and Gynaecology.

#### 229. Uterine Rupture during Labour.

V. COCQ and J. J. SNOECK (*Bruxelles-Médical*, January 1st, 1928, p. 269) record three cases of uterine rupture during labour, and describe in detail a fourth personal one. In one case the rupture was evidently caused by manual or instrumental intervention, death ensuing during the confinement. In another case the rupture was apparently spontaneous, and a subtotal hysterectomy was performed. The patient, a multipara aged 35, progressed favourably after the operation, but broncho-pneumonia supervening on the fifth day she succumbed in six weeks. The authors classify uterine rupture as incomplete, complete, and complicated with involvement of neighbouring organs; it may be of traumatic origin or occur spontaneously. They agree with Bandl that certain spontaneous ruptures in multiparae are due to an exaggerated development of the uterus, the result of former pregnancies, which by too strong and too frequent contractions can cause a tear of the lower segment. Factors predisposing to rupture are multiparity (only 6 to 12 per cent. occur in primiparae), neoplasms, cicatrices (the result of previous operations), degeneration of the uterine muscular fibres, and any factors causing abnormal resistance to the uterine contractions, such as retracted pelvis and hydrocephalus. Two important traumatic causes are version and ill-judged forceps application. The prognosis is bad, the maternal mortality being 60 per cent. and the foetal 96. The treatment in these cases, as soon as a diagnosis is made, is abdominal section followed most frequently by subtotal hysterectomy, though in exceptional cases suturing of the uterine tear is sufficient. Extraction of the child through the natural passage is indicated only when the presenting part is deeply engaged in the pelvis. The authors strongly deprecate version and the application of forceps to a non-engaged head, or before dilatation is complete. Internal podalic version in a uterus void of liquor amnii, and especially if preceded by forcible dilatation, is fraught with grave risks to both mother and infant.

#### 230. Early Carcinoma of the Uterus.

ACCORDING to L. CATTANEO (*Ann. di Ostet. e Ginecol.*, December, 1927, p. 1001) early uterine carcinoma may elude detection owing to the paucity of symptoms, the neglect to make a biopsy, or to insufficient care to examine the deep, as well as the superficial, portions of the suspect tumour; the investigation should extend laterally into the apparently healthy regions. He alludes to a case recently described by Lettelle in which endometrial fragments, removed by curetting from a patient with menopausal bleeding, were reported to show fungous endometritis with no sign of malignant disease. Microscopical examination after hysterectomy a few days later produced clear evidence of carcinomatous infiltration of the fundus, and inquiry showed that in this region the scraping had been superficial for fear of causing perforation. Cattaneo describes the case of a married nullipara aged 50, who complained solely of leucorrhoea following the cessation of menses two years previously. The physical signs were normal except that to the left of the external os was a papillomatous tumour the size and shape of a small bean and covered with intact mucous membrane. The tumour did not bleed on manipulation, and infiltration in the neighbourhood

was absent. Microscopical examination after biopsy showed regular papillary formations consisting of a vascular core covered by regular squamous epithelium. In two places, however, cell nests were present and the epithelium in the neighbourhood showed a tendency to multiple stratification and the presence of mitosis. Early malignant disease of the cervix being therefore suspected vaginal hysterectomy was performed. Microscopical examination of the cervix in the region subjacent to the papilloma now showed invasions by squamous epithelium within the lumen of the glands of the cervix and penetration into the adjacent connective tissue and myometrium.

#### 231. Causes of Uterine Haemorrhage.

R. MAGAREY (*Med. Journ. of Australia*, October 8th, 1927, p. 504) agrees with Whitehouse's classification of excessive uterine bleeding into (1) epimenorrhoea, or too frequent menstruation; (2) menostaxis, or too prolonged menstruation; (3) true menorrhagia, or too great a loss at a period otherwise normal; and (4) metrostaxis, or irregular uterine bleeding. Under extra-genital causes of haemorrhage he refers first to excessive thyroid action, and attributes menorrhagia at the end of lactation to a continuance of the increased thyroid activity of pregnancy; the appropriate treatment is radiation of the thyroid and the exhibition of calcium salts. He next mentions influenza, when the menorrhagia is only temporary. As regards the uterine causes, the retention of the products of conception is common even when the confinement has been normal; in inevitable abortion the author does not advise immediate curettage, but advocates packing the vagina tightly for twenty-four to thirty-six hours, dilating the cervix and stimulating uterine contraction; this facilitates the subsequent curettage and lessens haemorrhage. Under malignant causes of haemorrhage endocervical carcinoma is important, because it may be easily missed before the tumour has reached the vaginal surface; even a diagnostic curettage may fail to detect it, the only indication of its existence being the fusiform shape of the cervix from the external to the internal os. Non-malignant causes most commonly overlooked are: (1) small sessile cervical polypi, which are easiest found by inspection; (2) intrauterine polyp, often associated with small fibroids, and frequently missed at a curettage—these may cause temporary amenorrhoea, followed by profuse loss; (3) enlarged, thickened, and possibly lacerated cervix; (4) previous operations on tubes or ovaries, because the infection which necessitated operation has caused a fibrosis uteri; in such cases complete hysterectomy is necessary. The author has found treatment by radiation particularly useful for menopausal haemorrhage, especially if due to subinvolution and to fibroids. He adds that it should be remembered that the full effect of radiation is frequently delayed for several months, during which time menstruation may be quite irregular, and that for six weeks or so the patient may have a rather profuse leucorrhoea.

#### 232. Injuries of the Bladder during Labour.

B. OTTOW (*Zentralbl. f. Gynäk.*, November 12th, 1927, p. 2924) classifies vesical injuries during labour as contusions, pressure erosions, and lacerations. Contusions may cause oedema, which may be confined to the sphincter or extend to the trigone; they may be accompanied by multiple haemorrhages into the mucous membrane. This oedema varies in extent, and is usually infiltrative, but may be hollow in patches. Haemorrhages are commonest at the trigone and fundus. Such contusions are caused more by delay in the pelvic canal than at the pelvic inlet, and alteration in the tissues due to pregnancy must not be overlooked as a contributory factor. As the head descends the bladder is pushed upwards and the trigone and sphincter region are compressed between the head and symphysis; they are also pushed up over the advancing part, thus squeezing the soft parts between two hard resistances. Similar contusions may arise from, or be increased by, operative measures. Such contusions are apparent shortly after birth; they cause no constant symptoms, although haematuria is common. The rate of recovery varies greatly, but this bruising rarely causes fistula formation. Pressure erosions arise during the overcoming of discrepancy between the foetal head and the pelvis; the critical moment is at the pelvic inlet. The characteristic sites are in the fundus-trigone region and on the anterior wall; these are seen in flat pelvis. In "justo minor" cases the above pressure points are joined by bands. Cystoscopically pressure erosions of the trigone and fundus show all degrees from oedema to deep necrosis of the bladder wall. On the anterior aspect they are usually more superficial; in the sphincter area necrosis and fissures may be found. These pressure erosions frequently lead to fistulae, but in their absence the erosions heal during the puerperium. If they are superficial no scar is left, but if they are deep and extensive then sloughing and a secondary fistula may result,

becoming manifest a week after delivery. Fistulae appearing immediately after operative delivery are due to rupture of parts already weakened by pressure. Lacerations may occur during operative procedures, and are characterized by their ragged outline and absence of oedema. Cystoscopy is the only accurate means of investigating any suspicious case, and the risk of infection is lessened if it is performed at once before the lochia have started. A permanent catheter is the best means of preventing fistula formation and other sequelae; it should be left in for ten to twelve days. Should a fistula develop the catheter should be retained and in many cases the fistula will heal. No urinary antiseptics are given by the month, but once daily a small quantity of a silver preparation is instilled and left for some time in the bladder to prevent an ascending infection.

## Pathology.

### 233. The Pathology of Ossification.

R. LERICHE (*Bruzelles-Médical*, January 29th, 1928, p. 439), referring to a paper by A. Policard on osseous physiology (*ibid.*, p. 433), shows that an increased knowledge of the laws governing ossification have added to the pathology and treatment of many bone conditions. Two new ideas have been evolved. The first is that pathological bone formation, a metaplastic, humoral, non-cellular phenomenon, involves two processes—congestion with oedema of the soft peri- and par-osseous tissues, and rarefaction of the bone. The calcareous reparative material does not come from the blood stream but from the injured bone itself by the action of the congested and oedematous surrounding connective tissue. Dry tissues will not cause ossification, but only those modified by hyperaemia and oedema. The second idea is that all increased circulatory activity and all hyperaemia round a bone cause absorption. Congestion of the periosteum and reabsorption of the bone are the physiological conditions necessary for bone formation. Leriche illustrates these points by describing the repair of fractures in long bones, and the conditions existing after injury. All traumatism produces an active vaso-dilatation which is usually of short duration, but may be prolonged by various causes for several weeks; the author finds that in many cases where pain over the bone with difficulty of articular movement is experienced after injury without any apparent bone lesion, radiograms will reveal a considerable decalcification. This has been caused by the vaso-dilatation, but will not be followed by repair unless the circulation be modified. Osteogenesis and osseous rarefaction are, therefore, vasomotor phenomena, and these can be surgically treated. Leriche maintains that in certain conditions the formation of lime and the subsequent healing can be much accelerated by sympathectomy. In slow consolidation, as in the pseudo-arthritis, where osteo-synthesis and grafts have failed, peri-arterial sympathectomy produces a great transformation and ossification in ten to twenty days. In osteoporoses, where the bone is being absorbed, sympathectomy (peri-arterial) if the trouble is very peripheral, ramification if it is diffuse) after a phase of increased rarefaction, will cause speedy repair. Two cases are reported which show the benefits from these methods.

### 234. The Effect of Splenectomy on Experimental Infection.

P. MORETTI (*Giorn. di Batteriol. e Immunol.*, December, 1927, p. 805) has investigated the effect of splenectomy on the course of bacterial and spirochaetal infections in animals. In one experiment he injected subcutaneously two mice, one of which had had its spleen removed thirty days previously, with 0.5 c.cm. of blood from a patient with staphylococcal septicaemia. The splenectomized mouse became ill and was killed on the sixth day, a pure culture of staphylococci being recovered from the heart blood and liver. The control mouse remained well; it was killed on the twelfth day, and cultures of the blood and spleen were negative. In a second experiment three pairs of mice, one of each pair having been splenectomized, were injected with blood from three patients in different stages of undulant fever. One of the splenectomized mice died on the fourth day, and *B. melitensis* was recovered from the blood and liver in pure culture. The other mice remained well. In a third experiment two splenectomized and two normal mice were injected with blood from a patient suffering from spirochaetosis (*Spirochaeta duttoni*). It was found that in the splenectomized animals the spirochaetes appeared on the fifth day, and were present in the blood in fairly large numbers, whereas in the controls they did not appear in the blood till the eighth day, and were then present in only small numbers. Moreover, the intermissions were short and incomplete in the experimental, but clear-cut

and complete in the control animals. Finally, two white rats, one splenectomized and one normal, were injected with blood from a mouse infected with *Spirochaeta duttoni*. In the blood of the splenectomized animal a very few spirochaetes were found on the seventh day; the animal died two days later. In the blood of the control rat spirochaetes were never found microscopically, even though the blood proved infective to mice; the animal survived. From these experiments the author concludes that the effect of splenectomy is to diminish the resistance of the animal to experimental infection. In his opinion one of the activities of the spleen is to prevent bacteria which have gained access to the circulation from giving rise to a general infection.

### 235. Dissociation of Toxin-antitoxin Mixtures.

B. BUSSON (*Centr. bl. f. Bakt.*, January 16th, 1928, p. 183) criticizes a recent article by Gorochnikowa of Moscow, who maintains that dissociation of a neutral diphtheria toxin-antitoxin mixture cannot be brought about either by physical or chemical influences, and who explains the fatalities that have occurred after its administration by assuming that pure toxin was given by mistake. Busson points out that several workers have now shown that such a mixture may undergo dissociation, and that a considerable excess of free toxin may result. Working with old batches of toxin, he has found that the colloidal solution may separate into different layers, and he believes that the same may occur in a toxin-antitoxin mixture. Normally the union of toxin and antitoxin is reversible, but the author draws attention to the change that would occur if a certain amount of dissociated toxin or antitoxin was removed from a flask containing an originally neutral mixture; instead of the remaining substances combining again to form a neutral mixture they would give rise to a quite different end-product. Busson has observed similar alterations in toxin-antitoxin mixtures as the result of change of temperature. In practice it is known that the injection of toxin-antitoxin mixtures may prove fatal in children; such fatalities have been reported in America, Austria, and Germany. The author describes the case of a man who was severely ill with a high temperature and severe local disturbance after injection of a supposedly neutral mixture. He concludes that there is no doubt about the dissociability of toxin-antitoxin mixture; this conclusion is supported both by laboratory work and by practical experience in the field.

### 236. The Filterable Elements of Tubercle Bacilli.

J. VALTIS (*Presse Méd.*, January 28th, 1928, p. 113) describes experiments on the filterable viruses of tubercle bacilli with reference to their pathogenicity, culturable properties, the sensitivity to tuberculin, the immunity conferred by their inoculation, and their transplacental infection of the foetus. Working with guinea-pigs, and using filtrates of bacilli obtained from tuberculous sputa, pus, and cultures, he found that, in addition to the typical acid-resisting Koch's bacilli, there undoubtedly existed an ultra-microscopic form capable of passing through  $L_2$  and  $L_3$  Chamberland filters. In the filtrates, even after long centrifuging, no visible elements were detected, and cultures on special media remained constantly sterile. Intraperitoneal and subcutaneous inoculations of the filtrates caused an infection, sometimes transitory, of a special type and of very slow evolution, characterized by the presence of very marked sclerosed ganglionic lesions, and discrete visceral nodules, which contained typical tubercle bacilli. Their virulence, however, was so slight that it could not be increased by successive passages through animals. Valtis believes that with the exception of Vaudremer and Mile Togouroff no experimenter has succeeded in cultivating these filterable elements. The filtrates caused sensitiveness to intradermic inoculations of tuberculin, and produced a certain amount of immunity against an infection of average intensity. Valtis also demonstrated that tuberculous infection could be carried through the placenta to the offspring by these filtrates, typical tubercle bacilli being recovered from the foetal lesions.

### 237. Bacteriology of Dried Milk.

G. F. DICK AND GLADYS H. DICK (*Amer. Journ. Dis. Child.*, December, 1927, p. 1040) investigated the bacterial content of two samples of preparations of dried milk, following on an epidemic of enteritis in an institution in which infants received artificial feeds composed largely of dried protein milk. Cultures were made from broth suspensions plated on sheep's blood agar. A feed prepared with one sample was found to contain 22,000 living bacteria per c.cm., of which 11,000 were green-producing streptococci. With another sample a feed contained 9,000 living bacteria in 1 c.cm. with 7,000 green-producing streptococci. The authors emphasize the necessity for the pasteurization or boiling of powdered milk feeds.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

238.

### Insulin Poisoning.

B. DAHL (Norsk Mag. f. Lægevid., January, 1928, p. 40) records the first fatal case of insulin poisoning to be reported in Scandinavia—a woman, aged 52, who was admitted to hospital for severe diabetes, in a state of incipient coma. Under treatment by insulin the glycosuria and acidosis disappeared and considerable general improvement followed. On the ninth day of treatment, however, she neglected to eat the regulation amount of bread at lunch; half an hour previously she had been given 15 units of insulin. After lunch she went to sleep as usual, so that the ineffectual hypoglycaemic reaction escaped notice; three hours after the injection she was found in deep coma with a blood sugar of 0.025 per cent. In spite of the administration of adrenalin and glucose, whereby hyperglycaemia was produced (seven hours after onset of coma 0.380 per cent. and two hours before death 0.089 per cent.), death ensued in nineteen hours without a return of consciousness. No convulsions were observed. No special pathological condition was found at the necropsy, so that an overdose of insulin must be regarded as the cause of death.

### 239. Spirochaetosis Icterohaemorrhagica in the Dutch Indies.

ACCORDING to G. BAERMANN and E. SMITS (*Nederl. Tijdschr. v. Geneesk.*), December 10th, 1927, p. 2478) special attention has been paid during the last five years in the Central Hospital at Sumatra to febrile diseases caused by spirochaetes, with the result that they have collected about 390 cases, all due to the same organism and mostly of a mild character; there were, however, some moderate and some very severe forms presenting typical symptoms of spirochaetosis ictero-haemorrhagica. Almost all the patients were Javaese workmen employed in the rubber works, and only a few women were represented. The incubation period ranged from four to ten days. Nearly all complained of feeling tired, and very many of pains in various muscles. Apart from the severe cases the average duration of the disease was ten days. Jaundice, which developed on the third and fourth day, and usually not later than the sixth, was found in only 17 per cent. In 33 per cent. there were no renal symptoms; 42 per cent. had only slight albuminuria, and 25 per cent. had casts or red cells in the sediment. Haemorrhages, to which the disease owes its name, were limited to a slight conjunctival haemorrhage, petechiae, and bleeding under the gums. Definite jaundice was not always present in these cases. Infection was always traced to water, without rats taking part in the dissemination of the disease. The prognosis was remarkably good, as only four deaths occurred among 340 cases. Treatment was mainly symptomatic, but a polyvalent serum was used in the severe cases.

240.

### Purpura Fulminans.

H. KNAUER (*Jahrb. f. Kinderheilk.*, November, 1927, p. 1), who records an illustrative case, states that this condition was first given its name in 1887 by Heuvel, who defined its characteristic features as the absence of haemorrhage from the mucous membrane, the occurrence of extensive ecchymoses, an extremely rapid course, absence of complications, and lack of post-mortem findings, apart from general anaemia. Knauer's patient was a previously healthy girl, aged 6, who on the eighth day of a mild attack of chicken-pox developed the lesions of purpura fulminans on the lower limbs, and shortly afterwards passed bright red blood from the urogenital tract and rectum. Recovery followed repeated large transfusions. Scoury could be excluded as well as thrombopenia, since the number of blood platelets was normal. Knauer attributes the extensive haemorrhage in his case to very marked diminution of fibrinogen. There was complete absence of coagulation *in vitro* with a normal bleeding time.

### 241. Tuberculous Typhobacillosis in Adolescents.

T. PONTANO (*Il Policlinico, Sez. Med.*, January 1st, 1928, p. 1) records three cases, in patients aged 14, 17, and 20 respectively, who presented a special form of tuberculosis corresponding to the typhobacillosis of Landouzy. The clinical features were an acute onset with constitutional disturbance without localizing signs, prolonged irregular fever with slight enlargement of the spleen, absence of signs in the chest on

clinical examination, and late development of pleurisy with effusion, followed by recovery. Radiological examination, however, in such cases showed considerable enlargement of the lymphatic glands at the hilum similar to that met with in childhood. The condition, therefore, does not represent a generalized infection, but rather an infection of the pulmonary hilum, in which the lymphoid tissue has retained the characteristics of the lymphoid tissue of early life.

242.

### Testicular Mumps without Parotitis.

R. W. DANIELSON (*Journ. Amer. Med. Assoc.*, December 10th, 1927, p. 2041), who records an illustrative case, remarks that very few examples of the condition have been reported, the most complete account of it being found in Bathait's Paris thesis of 1918. Danielson's case was that of a man, aged 44, who had recently been engaged in riding bronchos and wood-hauling, but had not to his knowledge injured his testes in the slightest degree. He had bilateral uncomplicated mumps at the age of 9. Thirty-three years later he developed bilateral orchitis, six weeks after his wife and six children had had mild uncomplicated mumps. The diagnosis was made by elimination of other causes, such as syphilis, gonorrhoea, tuberculosis, and trauma, and the history of exposure to mumps.

### 243. Second Attacks of Scarlet Fever and Mumps.

T. REH (*Arch. de Méd. des Enf.*, December, 1927, p. 724) reports a second attack of scarlet fever in a girl, aged 10, who had had a previous attack three years before. On both occasions infection occurred during an epidemic and was followed by typical desquamation. In the recurrent attack, however, the temperature was hardly at all raised. A second attack of mumps occurred in a boy, aged 8½, who had had a previous attack seven years before at the same time as his sister. On the second occasion, however, his sister escaped, although she had to live in the same room as her brother. The case is of interest both on account of the early age of the boy at the time of his first attack and the immunity enjoyed by the sister.

244.

### Renal Complications of Influenza.

Q. CELLI (*Il Morgagni*, January 9th, 1928, p. 41), who records an illustrative case, believes that the occurrence of slight albuminuria in influenza is the rule and its absence is exceptional. Severe renal lesions, on the other hand, though they do exist, are not at all frequent. The prognosis is generally good, and the lesions rarely become chronic in previously healthy subjects. As regards the pathogenesis of these renal changes Celli considers the toxic factor the most important, though in certain cases the microbial factor cannot be excluded. Influenzal nephritis and nephrosis do not present any special characteristics to distinguish them from renal lesions due to other causes.

## Surgery.

245.

### Diagnostic Errors in Secondary Sciatica.

A. FRENKEL (*Zentralbl. f. Chir.*, February 4th, 1928, p. 274) reports four cases of the fairly common condition of sciatica secondary to other diseases. One, a man, after being treated for three months for left sciatica and then discharged as a chronic invalid, developed shortly afterwards a phlegmonous inflammation of the left buttock. The history and clinical appearance suggested that there was a necrotic tumour in the sacral region. This was confirmed by an operation, which relieved the pain and saved the patient's life. A lad, aged 18, was treated in the neurological department of a hospital for sciatica apparently due to some spinal deformity, though extension of the vertebral column was easy and painless. There was a tender spot over the spinous process of the third lumbar vertebra. Spondylitis posttyphosa was diagnosed and confirmed by radiography. After two months' orthopaedic treatment the patient was cured and fit for work. A woman, aged 45, with uterine carcinoma was treated by radiotherapy; three months later she developed sciatica, and vaginal examination showed an extensive secondary growth involving the left sciatic nerve. The fourth patient, who had been treated for sciatica for two years, was subsequently thought to have tuberculous hip disease or malignant disease; an exploratory operation revealed an inoperable sarcoma.

## 243. Tuberculosis of the Os Pubis.

N. TAGLIAVACCHÉ and L. A. WEBER (*Boll. y Trab. Soc. de Cir. de Buenos Aires*, December 7th, 1927, p. 927), who record an illustrative case of twelve years' duration in a man aged 31, assert that tuberculosis of the pubic bone is an uncommon affection, only one example being found among every thousand cases of surgical tuberculosis (Pieromans). The onset generally occurs before the age of 30, rarely later. It is not more common in one sex than in the other; trauma does not appear to be of much significance, but pregnancy and parturition are more important since they are liable to reactivate a dormant tuberculous process. The localization depends on whether the osteitis develops before or after puberty. In the former case the body and ramus of the pubis are affected, and in the latter the angle, spine, or symphysis. The lesion may assume a circumscribed or cavernous form, which may give rise to sequestra and is comparatively frequent and diffuse, or, more rarely, it may be of a periosteal type; the former is manifested by a rarefying osteitis and the latter by an enlargement and caseous transformation of the periosteum. Abscesses usually develop, with the same characteristics as those of other tuberculous processes; they spread to neighbouring regions, giving rise to fistulae, which may open in the labia majora, adductors of the thigh, or Scarpa's triangle. The onset is usually insidious. The pain varies in degree, but is usually not intense, and may be situated either in the pubis itself or in adjacent regions, such as the groin, hips, or inner side of the thigh. The patient may show a certain degree of flexion and adduction of the thigh. The movements of the limb are usually preserved, apart from adduction, which is occasionally limited. Limping is rare and is most frequently found in children. A cold abscess, which often occurs and may be found in various situations, may be the only manifestation of the disease. The most important complications are involvement of the symphysis, hip-joint, and bladder. The diagnosis must be made from neuralgia, simple or traumatic periostitis, inguinal or crural adenitis, and osteomyelitis of the pubis. Treatment does not differ from that of other osseous localizations of tuberculosis.

## 247. Acute Dilatation of the Stomach treated by Gastrostomy.

MATRY (*Bull. et Mém. Soc. Nat. de Chir.*, January 21st, 1923, p. 10) records a case of acute gastric dilatation in a lad aged 15. After a large meal his abdomen became enormously distended, and he was brought to hospital in a serious condition. Under spinal anaesthesia gastrostomy was performed, but the patient died shortly afterwards. At the necropsy the duodeno-pyloric flexure was found fixed high up in contact with the liver, and the cause of the condition probably lay in this congenital anomaly. The condition of acute dilatation of the stomach has been seen in varying circumstances. It is best known as a complication following operation, or associated with acute febrile conditions such as typhoid fever, or following accidents. Eating a large meal too quickly is also given as a cause. An interesting feature in some of these cases is the absence of vomiting, which is difficult to explain unless it is due to atony of the stomach. The diagnosis is easily made by the enormous distension of the upper part of the abdomen. Treatment by surgical operation, or by the stomach tube, or by posturo, has not given good results as a rule.

## 248. Retained Ureteral Catheter.

D. N. EISENDRATH (*Journ. Amer. Med. Assoc.*, December 24th, 1927, p. 2170) advocates a more widespread use of the retained ureteral catheter in the treatment of acute and chronic (non-tuberculous) pyelonephritis; for the relief of obstructive anuria and the severe pain in acute ureteral block by calculus or kinking; in cases of ureteral injury following operations; and as a method of drainage of the kidney after the repair of a vesico-vaginal fistula. Illustrative cases are given from a relatively large number treated during the past four years. The author uses small (5 F.) opaque catheters, only one being inserted, since the use of two lying side by side or one large occluding catheter was not found to possess any advantage. Irrigation of the renal pelvis was seldom necessary because ample drainage was provided through the lumen or alongside the catheter. Such catheters have been left in position as long as two weeks, there being no time limit other than until the temperature has been normal and the urine clear for five days. Eisendrath adds that any tendency for the catheters to be expelled when the bladder becomes distended can be overcome by the insertion of a urethral catheter in order to avoid the accumulation of urine in the bladder. Results have been most gratifying, and the author considers that the method deserves to be better known.

## Therapeutics.

## 249. A Precaution in Blood Transfusions.

W. V. BREM, A. H. ZEILER, and R. W. HAMMACK (*Amer. Journ. Med. Sci.*, January, 1928, p. 96), from their experience with over 4,000 blood transfusions, recognize three types of reactions: the febrile, with or without chills; those due to use of a wrong group; and the anaphylactoid. The last two are rare, the common one being the first, but current theories as to its causation are still speculative and have no prophylactic value. A recent case, which is fully described, led the authors to believe that the use of fasting donors might help to prevent these febrile reactions. The patient suffered from recurrent haemorrhages due to duodenal ulcer, for the effects of which blood transfusions were administered. When these were given from non-fasting donors severe febrile reactions occurred, but when fasting donors were used there were no reactions in four transfusions and only a mild one in a fifth. On one occasion, when a transfusion was being given two hours after the donor had eaten a hearty protein meal, including beef steak, the patient had a severe chill and fever reaction, beginning two hours after the transfusion, and haemoglobinuria was noted three hours later. No grouping error could be discovered. The authors suggest, therefore, that some of these febrile reactions may be due to toxic products in the donor's blood, and that they may be avoided by requiring the donors to fast for a certain time before the transfusion. In the case recorded an overnight fast seemed to be sufficient.

## 250. Myosalvarsan in the Treatment of Syphilis.

J. FABRY (*Méd. Welt*, January 7th, 1928, p. 20) prefers myosalvarsan to the older arsenobenzol preparations for the reason that in many cases, especially among women and children, the veins are difficult to locate, and that intramuscular injections of the arsenobenzols are frequently painful and in a considerable number of cases have produced extensive necrosis of muscle and fascia. Myosalvarsan is, however, equally suitable for intravenous, intramuscular, and subfascial injection, but intramuscular or subcutaneous injections are less potent than are intravenous injections. Fabry has seen no case of necrosis of muscle or fibrous tissue after the injection of myosalvarsan, and he regards it as an important addition to the list of available drugs. The best site for intramuscular injections is in the gluteal region, as far as possible away from the sciatic nerve. He recommends its administration in distilled water or in lactose solutions. Intramuscular injection is contraindicated in recent infections, but intravenous injections offer a rapid cure. Intramuscular injections are said to be suitable for all cases of parasyphilis, aortic aneurysm, and cerebral or visceral syphilis, especially in the specific cachexia and the arsenic-resistant forms of the disease. In opisthical injections there is some cumulative action, since the deposit at the site of injection is but slowly absorbed; the injections should not be given, therefore, at shorter intervals than eight to ten days. A cannula of at least 3 cm. in length should be employed.

## 251. Treatment by Experimental Infection.

P. MORETTI (*Riv. med.*, January 2nd, 1928, p. 2) remarks that the therapeutic action of experimental infection has not yet been satisfactorily explained. It is at present impossible to say whether the beneficial effects are due to the fever, shock, focal reaction, or a special hypothetical antagonism between different viruses. He records a case of myeloid leukaemia in a woman aged 50, and of chronic articular rheumatism in a man aged 23, both treated by subcutaneous injections of *Spirochaeta duttoni*, the micro-organism of African relapsing fever. Transient improvement occurred in the first case and a complete cure in the second, after other methods of treatment had failed. Moretti emphasizes the importance of keeping in stock a strain of *Spirochaeta duttoni* or the special virulent mosquitoes which, under suitable conditions, retain their infectivity for a considerable period. Experimental relapsing fever is a much milder disease than malaria, does not give rise to complications or changes in the blood picture, and is readily cured by the oral administration of stovarsol.

## 252. Antitoxin Treatment of Scarlet Fever.

R. C. ELEY (*Amer. Journ. Dis. Child.*, January, 1928, p. 14) reports a series of 465 consecutive and unselected cases of scarlet fever; of these, 215 received either antitoxin or a combined antitoxin and bactericidal serum, the latter giving the better results. Moderately slight cases did not receive the treatment for fear of a serum rash, which would be worse than the disease. Adrenaline, ophedrine, and in some cases morphine, were given when a rash developed. The value of the treatment is said to be definite. The temperature falls to 100°F. or below within twenty-four to forty-eight hours, and

the entire clinical picture is strikingly changed for the better. Where no improvement is apparent after forty-eight hours it is advised that a second dose be given. Cases that do not respond to treatment are possibly due to strains of streptococci not represented in the preparation used. Eley recommends that severe cases should be given the antitoxin either intravenously, or intravenously and intramuscularly combined. The dose depends on the severity of the case and the age and size of the patient. In the cases detailed in this series the dose ranged from 2,500 to 10,000 units.

#### 253. An Analgesic Preparation.

H. V. DE LAGUERIE (*Med. Journ. and Record*, December 7th, 1927, p. 667) calls attention to the analgesic advantages of elbaine, a combination of dial and amidopyrine, and refers to its tolerability, duration of action, and ease of administration. He states that it can be given either orally in tablet form, each consisting of dial 0.03 gram and amidopyrine 0.22 gram, or in 2 c.cm. ampoules for hypodermic use, containing dial 0.06 gram and amidopyrine 0.44 gram. Experimentally it has been shown to be of distinct advantage in cases where it is desired to relieve pain by calming a peripheral nervous excitation without disturbing sensibility or consciousness. In many cases it is said to be preferable to morphine, since there is no risk of addiction or craving, and it may be administered frequently for an almost indefinite period. No nausea, headache, or stupor on awakening was observed, and constipation and other after-effects of morphine were avoided. Its calming effect upon morphine addicts enables the period of deprivation to be passed without suffering. The author recommends its use for the relief of pain in cases of tuberculosis with cavities and haemoptysis, in asthmatic attacks, hepatic and renal colic, and for the relief of epileptic attacks or the treatment of morphone addiction.

#### 254. Auto-haemotherapy in Spasmodic Coryza.

A. L. BENITO (*Arch. de med., cir. y esp.*, January 14th, 1928, p. 58), who records two illustrative cases in patients aged 29 and 35, considers spasmodic coryza to be a local manifestation of a general disturbance due to one or more various external irritants acting on the hypersensitive ocular, nasal, and bronchial mucous membranes of individuals who directly or by heredity are neuropathic or gouty. The predominant symptoms are nasal obstruction, sneezing, and rhorrhoea, which are accompanied by photophobia, epiphora, and asthmatic attacks, and are followed by the expectoration of frothy sputum. Benito's method of treatment consists in withdrawing 10 c.cm. of blood from the vein of the elbow and injecting it without any further manipulation into the external aspect of the thigh. The injections are given every two or three days, from three to five usually being sufficient to produce a cure. The treatment was combined with resection of the nasal spurs, not only to re-establish permeability of the nostrils, but also to modify the hypersensitiveness of the nasal mucous membrane. It was found that better results were obtained by this combined treatment than by resection or cauterization alone.

## Anaesthetics.

#### 255. Gas-Oxygen and Rectal Ether Anaesthesia.

J. F. L. KILLORAN (*St. Michael's Hosp. Med. Bull.* (Toronto), December, 1927, p. 76) recapitulates briefly Gwathmey's technique for rectal ether anaesthesia. In this technique preliminary cleansing enemas are given in the evening preceding and the morning of the operation, and premedication with morphine, chloroform, or paraldehyde one hour before the operation is advised. A 65 per cent. solution of ether in olive oil is administered one hour before the operation in a ratio of 1 oz. per 20 lb. of body weight. As in respiratory administration, the reactions to this drug vary greatly, the danger signs being cyanosis, diminution of reflex activity, and embarrassed respiration. The amount of detail in the method has rendered it unpopular. The employment of nitrous oxide and oxygen for surgical anaesthesia has much increased during recent years, and the improved appliances permit the synchronous administration of ether, gas, and oxygen vapours. In a number of cases, particularly where inflammation is present in the respiratory tract, the use of ether is not desirable. By the addition of nitrous oxide and oxygen, anaesthesia with muscular relaxation can be produced in any operation with a smaller rectal dose of ether. The technique has been somewhat changed. Mineral oil, instead of olive oil, is now used, and a 50 per cent. solution of ether in liquid paraffin is given in a ratio of 1 oz. per 50 lb. of body weight. In St. Michael's Hospital a mixture containing 1 oz. each of ether and paraffin with

1 drachm of paraldehyde is made up and given in the quantity prescribed an hour or so before the operation with a hypodermic injection of morphine, the latter being repeated half an hour later if desirable. By this method deep or light anaesthesia can be obtained, a greater percentage of oxygen can be given, and there are no dangerous periods of protracted cyanosis. It can be used wherever gas and oxygen is indicated, except in diseases of the lower bowel such as colitis.

#### 256. Anaesthetic Properties of Hedonal.

J. DONALD (*Brit. Journ. Anaesthesia*, January, 1928, p. 112) discusses the advantages, disadvantages, and physiological action in animals of hedonal, which is methyl-propyl-carbinol-urethane. Its advantages are as follows: (1) There is little or no excitement during the induction of anaesthesia by intravenous injection. (2) Great muscular relaxation is obtained. (3) It has a diuretic action without albumin, haemoglobin, or casts appearing in the urine. (4) Fatty degeneration does not occur in the liver, kidneys, or heart after its use. (5) There is no irritation of the respiratory tract because hedonal is not excreted by the lungs. (6) It has special advantages in cases of low tension or haemorrhage. (7) When used as a precursor to chloroform the quantity of the latter can be greatly reduced. The disadvantages, on the other hand, are that the apparatus for intravenous anaesthesia is cumbersome, the drug is unsuitable for conditions of high tension and for plethoric patients, and its use in very long operations is sometimes followed by oedema in pendulous parts.

#### 257. A Modified "A.C.E." Anaesthetic Mixture.

C. W. HARNED (*Anaesthesia and Analgesia*, December, 1927, p. 285) describes under the name of "alkoform" a mixture of one part of alcohol, two parts chloroform, and three parts ether, to which sufficient ether is added to make the specific gravity exactly the same as distilled water at 70° F. This definite proportion of ether is said to give better clinical results than is the case when either more or less ether is present in the solution; anaesthesia is produced more quickly and the sleep is more natural. There is also less mental and physical excitement, less perspiration, less bronchial irritation, and recovery is more rapid and much freer from nausea and vomiting. The destructive changes in the blood, kidneys, and liver by ether alone are markedly reduced, almost to a minimum, by the action of alkoform when given as a warm dry nebulized vapour. The alcohol seems to dilute the chloroform vapour, modifying its action. The average amount of alkoform required per hour is about 1½ ounces, and this small amount of anaesthetic, coupled with the masking of the objectionable ether odour, largely accounts for the lessened nausea and vomiting. The time of recovery ranges from three to twenty-five minutes, depending upon the depth and length of time of the anaesthesia. Alkoform is said also to possess greater analgesic properties than either chloroform or ether, and to be valuable therefore in obstetrics. Owing to the difference of volatility of the three agents in the solution, it is necessary that some means, other than evaporation, be devised to ensure that the gas or vapour will contain each in exactly the same proportions as in the liquid, and Harned recommends the Hinkle anaesthetic machine as being excellent for this purpose, owing to its nebulizing action.

## Obstetrics and Gynaecology.

#### 258. Labour in Contracted Pelves.

ALICE F. MAXWELL (*Journ. Amer. Med. Assoc.*, December 17th, 1927, p. 2088) classifies a pelvis as flat if the diagonal conjugate measures less than 10.9 cm., as generally contracted if the diagonal conjugate measures less than 11.4 cm., and as funnel-shaped if the distance between the tuberosities of the ischia measures less than 7.9 cm. Judged by these standards pelvic contractions occurred in 252 out of 6,500 deliveries under her control. She found that women with a generally contracted or funnel-shaped pelvis had smaller babies than women with flat pelvis. Her experience taught her that one out of every two women with a small pelvis was a potential candidate for operative delivery, and with this possibility in view she considered it imperative that every patient should be given detailed instructions as to proper hygiene of the birth canal during the last month of pregnancy. She emphasizes the point that trial labour has vaguely defined time limits, the real test commencing only when the cervix is completely dilated; it should not be prolonged beyond the limits of the patient's endurance. Cervical rigidity, feeble infrequent uterine contractions, and occipito-posterior presentations prolong labour, weaken the woman's power of resistance, and cause exhaustion before the value

of fetal labour can be determined. In view of the serious foetal and maternal mortality she is of opinion that high forceps delivery should be discarded; although until recently this was frequently the only method of delivery available when maternal exhaustion compelled delivery, her present policy in the management of contracted pelvis is conservative. The patient is allowed to go into natural labour; the progress is determined by rectal examination only, and in the event of it being unsatisfactory the child is delivered by a low cervical section.

#### 259. Bilateral Ovarian Aplasia.

W. BAER (*Zentralbl. f. Gynäk.*, December 17th, 1927, p. 3241) describes the case of a single woman, aged 23, who sought treatment for purulent vaginal discharge and abdominal pain. The body showed distinctly male characteristics: the shoulder girdle was broader than the pelvic girdle, the breasts were entirely undeveloped, hair was absent from the axillae and sparse on the pubes, the labia majora were small and the labia minora almost undeveloped. The hymen was intact and the vagina was narrow, but the infantile uterus admitted the sound for 3.3 cm. The symptoms were proved to be due to cervical gonorrhoea, probably contracted from a sister with whom she slept; the patient, who was sexually indifferent, had not had intercourse. On account of the difficulty experienced in dilating the infantile cervix the infection proved to be very resistant to local treatment. It was thought that abdominal operation was justified and the uterus and adnexa were extirpated. The specimen showed a uterus of the same size as that of a full-term foetus, and two nodules the size of peas occupied the position of the ovaries. Microscopically it was found that these nodules did not resemble ovarian tissue, but consisted of large cells like those of the glomerular zone of the suprarenal cortex. The endometrium showed only rudimentary gland formation, as well as an intense inflammatory infiltration.

#### 260. Ruptured Ectopic Gestation.

C. H. GORDON (*Amer. Journ. Surg.*, November, 1927, p. 456) states that neither the etiology nor the pathology of ruptured ectopic gestation is understood, and that treatment depends upon accurate diagnosis, which seems to present considerable difficulty. Most cases require operation, though a few patients recover without it. In a series of 120 consecutive cases collected by the author at two hospitals, 62 occurred on the right side and 58 on the left. In nearly all the cases there was vaginal bleeding; the average period of amenorrhoea was six weeks. Pain is constant, and with bleeding is the most important factor in diagnosis. A definite mass was palpable in 78 per cent. of the cases, while pain on moving the cervix was reported by nearly all the patients. Drawing the cervix forward caused intense pain and is a positive sign in diagnosis. Breast signs are occasionally present and help in the diagnosis of pregnancy. Pre-operative treatment consists in rest, the administration of morphine, and, in some cases, in transfusion of blood. The operative treatment consisted in removal of the tube alone in 75 cases, and of the tube and ovary in 36 cases. In 6 cases double salpingectomy was performed, and in 2 cases of interstitial rupture the uterus was removed. Gordon thinks that the mortality will be still further reduced by care before operation; in the present series there were two deaths.

### Pathology.

#### 261. The Nature of Herpes.

REMARKING that the theory of Bokay and Netter as to the identity of the virus of varicella and herpes is still undetermined, R. BOULIN (*Rev. de Méd.*, No. 8, 1927, p. 1029) reports a case of generalized herpes in illustration of his views. Between typical herpes, unilaterally confined to certain nerve areas, and these atypical types, many intermediate forms exist, from the hemiplegic herpes of Fournier to the aberrant ones described by Minet and Ledereq. Generalized herpes, of which 45 cases have been reported, including the present one, is characterized by two distinct eruptions: the one, atypical herpes, consisting of reddish, anaesthetic, painful patches with one or more nerve distributions, and studded with groups of vesicles; the other comprising isolated vesicles or papules on the normal skin and not on the erythematous patches, devoid of all pain and anaesthesia, and diffused over the whole body independently of any neural localization. The herpes patches always appear first, and the general eruption four to twelve days later. The latter may present various forms, such as erythematous macules, papules, vesicles, or bullae, but they always lie on the healthy skin, and dry up without any trace remaining, while

the herpetic areas become haemorrhagic and necrotic, and leave an anaesthetic cicatrix; nervous complications are, however, exceptional. Three theories are held as to the pathogenesis of this affection. According to the first one the herpes indicates a virulent infection of some ganglia by the virus, while the generalized eruption represents its dissemination along all the ganglionic chains and the infection of distant isolated cells. The ordinary theory, which Boulin supports, attributes to the herpes a ganglionic localization of the virus, and to the general eruption its dissemination by the blood stream. Herpes, then, is a trophic trouble due to the presence of the virus, and this theory explains its first appearance as vesicles and the absence of neural distribution and sensory complications in the general eruption. Netter holds that both eruptions are caused by the same virus, acting in the one case by ganglionic localization and in the other by septicaemic diffusion, that this common virus is varicellous, and that the general eruption is true varicella.

#### 262. Virulence of the Diphtheria Bacillus.

A. A. PINTO (*C. R. Soc. de Biologie*, January 20th, 1928, p. 159) gives an account of two diphtheria-like bacilli the virulence of which was altered by passage through the guinea-pig. The first came from the throat of a woman who was not suffering from, and who had not been in contact with, diphtheria; the second came from the throat of a woman who likewise was not suffering from diphtheria. Both strains on isolation appeared to be diphtheroids; they were arranged in palisades; they did not give Neisser's stain; they fermented no sugars; and they were avirulent to guinea-pigs in a dose of 3.5 c.cm. of a twenty-four-hour broth culture. Attempts were made to exalt the virulence of these strains. Growth from a serum culture was washed off in a little saline solution, mixed with 10 c.cm. of 35 per cent. gelatin, and injected intraperitoneally into guinea-pigs. Cultures were made from the heart blood or peritoneal exudate of the animals, which died, and injected into fresh animals. At the commencement of the passage experiments the lethal dose of these organisms was 16 serum slopes. After the first strain had been passed through twenty guinea-pigs it proved fatal in twenty-four to thirty-six hours when injected intraperitoneally with gelatin in a dose of one-tenth of a serum slope; injected without gelatin it was not virulent. The second strain, after being passed through eighteen guinea-pigs, likewise proved fatal in a dose of one-tenth of a serum slope; but it was also fatal when injected subcutaneously without gelatin. Examination showed that the first strain had not altered morphologically; it still fermented no sugars, was not agglutinated by an antidiphtherial serum, and was not neutralized by an antitoxin serum. The second strain, on the contrary, had become morphologically like the diphtheria bacillus; it fermented glucose, maltose, dextrin, and glycerol, was agglutinated to a titre of over 1 in 10,000, and was neutralized partly by an antitoxin serum. The author considers that his second strain was an avirulent diphtheria bacillus, and that its virulence was restored to normal by passage through the guinea-pig.

#### Local Immunization against Anthrax.

G. ROVIDA and E. SCHWARZ (*Lo Sperimentale*, January, 1928, p. 569) have investigated the truth of Besredka's views on local immunity to anthrax. The anthrax bacillus was grown for five to eight days in broth, filtered through a Chamberland candle, and tested for bactericidal power; experiments conducted *in vitro* and *in vivo* showed that such filtrates had only a slight inhibitory influence on the growth of the anthrax bacillus, and little or no effect on its virulence for guinea-pigs. A series of guinea-pigs was then vaccinated with filtrates of anthrax cultures. One group was injected subcutaneously, another group intracutaneously, and a third group was treated by rubbing the filtrate on to the shaved and scarified skin of the abdomen, three vaccinations being made at intervals of five days. All animals, together with uninoculated controls, were injected with a loopful of a twenty-four-hour culture of *B. anthracis* five days after the last of the injections being made by the various methods. The seven control animals died in 36 to 62 hours; the seven animals vaccinated subcutaneously died in 36 to 60 hours; of the fourteen animals vaccinated intracutaneously ten died in 36 to 72 hours; and of the six animals vaccinated percutaneously five died in 48 to 62 hours. Thus all the animals died except four of those vaccinated intracutaneously and one of those vaccinated percutaneously. To test whether these survivors were immune they were inoculated five days later in the same way as before with a living anthrax culture; all of them died in three days. It would appear, therefore, that if there is any immunity conferred by inoculation of the skin with broth filtrates it is very slight and transitory.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 264. Hemiplegia in Cerebro-spinal Fever.

F. BONNEL (*Journ. de Med. de Bordeaux et du Sud-Ouest*, February 10th, 1928, p. 99), who records an illustrative case, remarks that central paralyses are not very frequent in meningococcal infection. They generally appear at the commencement of the disease in the course of the first six days, and occasionally after convulsions or Jacksonian epilepsy. As a rule the paralysis takes the form of hemiplegia which closely resembles a hemiplegia of vascular origin. The hemiplegia, which generally affects the whole of one side, is flaccid at first, but soon becomes converted into a spastic form with Babinski's sign, exaggeration of the tendon reflexes, and ankle clonus. The facial paralysis involves chiefly the muscles supplied by the lower branch of the facial nerve, with comparative immunity of the orbicularis palpebrarum and frontalis muscles. Treatment, which is that of meningococcal septicaemia, should consist of injection of antimeningococcal serum by the intrathecal, intravenous, and subcutaneous routes. Bonnel's case occurred in a soldier, aged 21, who developed complete left hemiplegia on the fourth day of meningococcal meningitis which had been treated by antimeningococcal serum. The paralysis, which was at first flaccid, became spastic, but terminated in almost complete recovery.

### 265. The High Infantile Mortality of Large Families.

K. FRIEDJUNG (*Wien. klin. Woch.*, December 15th, 1927, p. 1578) reviews the literature illustrating the high infantile mortality characteristic of large families, and records his own observations, which are based on the study of 100 working-class women in Vienna, each of whom had given birth to six or more children in the course of the last four years. The fertility of many of them was extraordinarily high; five had been pregnant twenty to twenty-five times, and seven sixteen to nineteen times, and another twelve had had more than fifteen pregnancies each. The whole series had had 1,033 pregnancies, ending in the birth of 885 living children and 148 miscarriages, so that each mother had an average of 10.33 births. Of the 885 living children, however, 330 had died by September 30th, 1927, so that, including the 148 miscarriages, 46.27 per cent. of the pregnancies had been a dead loss to the State. Of the 100 mothers only 11 had not lost a child and 89 had lost one or more, as is shown by the following examples. One mother lost 16 out of 24 children born alive, and others lost 12 out of 19, 10 out of 13, 9 out of 11, 7 out of 9, 6 out of 8, 6 out of 7, and 3 out of 6. Of 115 living children born to nine mothers 81 died and only 34 survived. The causes of this high mortality are to be found in overcrowding, lack of cleanliness and ventilation, and greater liability of infection, especially tuberculosis. In a considerable proportion of cases the death of a child was due to an accident owing to lack of proper supervision.

### 266. Measles and Tuberculosis.

O. MARVEL (*Tidsskrift f. d. Norske Lægeforening*, February 1st, 1928, p. 105) has checked the old clinical dogma that measles is a frequent activator of tuberculosis, by means of certain statistical observations which do not bear out this teaching. He investigated the records of 208 children treated during the past ten years at the Rikshospital in Oslo. In all of them tuberculosis was diagnosed with more or less certainty. In 75 cases (36 per cent.) there was a history of measles, and in 12 there had been an interval of about a year between the outbreak of the measles and the admission to hospital. In 7 cases this interval was only two to four months, and in 4 the measles had broken out just before admission. In two cases there had been signs of tuberculosis before the outbreak of the measles. Thus, altogether there were only 9 out of the 208 (4.3 per cent.) in whom tuberculosis would seem to have been stirred into activity by the measles, whereas there were 66 children (31.7 per cent.) who contracted measles without immediate ill effects. The author has also investigated the notifications of measles and tuberculosis in Oslo with a view to ascertaining whether severe epidemics of measles were or were not followed by an increase in the number of cases of fatal tuberculosis, notably tuberculous meningitis. The notification of open tuberculosis was not compulsory in Norway before 1900, but for the past thirty-one years records were obtainable of the incidence of measles and tuberculous meningitis. As the graph prepared by the author shows, the incidence of measles varied greatly from year to

year in the period under review, but the incidence both of new cases of tuberculosis and of deaths from tuberculous meningitis during periods immediately following severe outbreaks of measles was not unusually high. In fact, while the incidence of measles showed wide fluctuations, ranging from 4 cases in 1918 to 2,650 cases in 1902, that of tuberculosis was highest about the end of last century, since when it has shown a tendency to decline. The author adds that Wilhelm Boisen (*Zeit. f. Kinderheilk.*, Bd. xl, 1926, p. 352), after reviewing 162 cases observed in his hospital in Düsseldorf in the period 1908-24, concludes that though measles, like other diseases, may weaken the body it does not stir tuberculosis into activity wholesale.

### 267. Encephalitis Following Diphtheria.

A. QUERIDO (*Nederl. Tijdschr. v. Geneesk.*, January 14th, 1928, p. 181), who records an illustrative case, remarks that the nervous disturbances following diphtheria are of four kinds: (1) paralysis of the peripheral nerves, (2) haemorrhages in the central nervous system owing to changes in the walls of the vessels, (3) emboli in the cerebral vessels, and (4) paraneuronal inflammation of the central nervous system. The last variety, according to the literature, appears to be the rarest. Querido's case occurred in a nurse, aged 20, who, on the eighth day of an attack of diphtheria, complained of severe headache, showed an inclination to vomit, and had slight twitching of the right hand. The knee and ankle jerks were brisk, and Babinski's sign was present in the right foot. Lumbar puncture gave issue to a clear and sterile cerebro-spinal fluid. The symptoms gradually subsided in the course of the next few days and complete recovery followed. Haemorrhage and embolism could be excluded by the short duration of the symptoms. Meningitis was put out of court by the absence of pain and Kernig's sign, and the condition of the cerebro-spinal fluid. Encephalitis therefore appeared to be the most likely explanation, the lesions being situated in the front part of the left internal capsule.

### 268. Acidosis in Athletes.

H. A. SALVESEN (*Norsk Mag. f. Lægevid.*, February, 1928, p. 121) made studies of the acidosis in young athletes after running various distances—namely, 100 metres, 400 metres, 1,500 metres, and 10,000 metres; it was found to be most pronounced after a 1,500 metre race. There was no relation between the degree of acidosis and previous training or the time taken by the race. From the body weight and lowering of the alkali reserve it was calculated that large amounts of organic acid (lactic acid) circulated in the organism after the race. Only a small part of this acid was excreted in the urine during and after the race; after a 10,000 metre race even less acid was excreted than during the control period.

## Surgery.

### 269. Extrapyrarnidal Symptoms following Accidents.

A. BARKMAN (*Acta Med. Scand.*, January 30th, 1928, p. 63) has observed that in many cases of accidents a most careful examination may be necessary in order to diagnose correctly the resulting lesion, and reports an instance of an incorrect diagnosis. The patient was a miner who, four years previously, had fallen down a mine shaft. When found he was semiconscious, but completely recovered his senses soon afterwards. During a three weeks' confinement to bed he complained only of soreness and stiffness of the back and upper extremities and of pain in the right knee. Later, on leaving bed, weakness in the left leg and sharp pains and trembling in the right arm were felt; paresis in both arms and the left leg, and trembling—most marked in the right arm but present over the entire body on exertion—were also noted. The patellar reflex, present on both sides, was exaggerated on the right. Since there was no evidence of any organic origin of this syndrome a diagnosis was made of traumatic neurosis. The patient continued incapable of heavy work, and on examination four years later showed trembling of the right arm, tonic contraction of the right hand on movement, stiffness of the arms and right leg, and pains in the right flank, along the inner sides of the thighs, and in the left half of the head. These symptoms were increased by exertion, and the muscular rigidity, myotony, and trembling indicated an extrapyramidal lesion. Further examination revealed that, on walking, the left leg remained stiff, causing a peculiar limping, and the left arm moved

normally, while the right was abducted at the shoulder and flexed at the elbow. The plantar reflex was normal on the left side but absent on the right. Many muscles of the right arm and lower extremities gave myotonic or myodystonic electrical reactions. After treatment by electricity and suggestion these symptoms abated, but they soon returned in an exaggerated form, thus showing that the condition was not, as in hysteria, of psychogenic origin, but was due to a lesion of the extrapyramidal motor area, possibly a tear of the cerebral substance or haemorrhage. Barkman discusses the paradoxical kinesia of Souques and Jarkowski, and concludes that the position of the extrapyramidal area, in equilibrium between the pyramidal tracts and the higher nervous, easily explains the fact that lesions of this area give rise to functional troubles of both organic and psychogenic origin.

#### 270. Abdominal Incisions.

ACCORDING to I. M. BOYKIN (*Annals of Surgery*, January, 1928, p. 74) the observation of a few simple rules renders it possible to leave the abdominal wall as strong and free from defects after an operation as it was previously. The incisions usually employed in the upper abdomen and in the pelvis are through the right or left rectus muscle or through the linea alba. An incision which splits the muscles produces a permanent defect. Mid-line incisions are said to be defective also, as they provide only one fascial plane to suture, which is not sufficient to ensure security. The paramedian incision is considered the most satisfactory. In gall-bladder operations a right paramedian oblique incision is useful; this begins across the mid-line and extends to beyond the linea semilunaris below the umbilicus. The muscle is reflected outwards and gives ample exposure. For the appendix a transversal incision is made at the level of the anterior superior spine of the ilium; the aponeuroses of the oblique muscles are split in the direction of the skin incision, the rectus drawn inwards, and the peritoneum is opened for the whole length of this incision. It is best to drain near the linea semilunaris. Secure and accurate suturing is necessary to leave the abdominal wall free from defects.

#### 271. Epithelioma of the Urethra.

ACCORDING to R. WURNISER (*Journ. d'Urol.*, December, 1927, p. 437) cancer of the urethra is a rare condition, and cases occurring in the posterior urethra are usually only recognized too late for treatment to be effective. It appears in patients between 50 and 60 years of age, and frequently follows some previous inflammatory condition of the urethra. The first sign may be a urethral discharge which is followed by a purulent fistula even before a swelling has been recognized. There may be difficulty of micturition and all the symptoms met with in a case of stricture. Later a perineal tumour may be detected, and also pain and haematuria, after which a fistula develops. Wurniser thinks that to diagnose the condition all painful strictures of the urethra should be examined with the urethroscope. He adds that the effective treatment of the condition depends on early diagnosis. In cancer of the penile urethra the urethra may be excised in early cases, or the penis be amputated. When the growth involves the perineal urethra extensive excision may be tried; where this is not possible local removal and cautery or radium applications should be employed. In some cases a cystostomy may be the best treatment to relieve pain and retention.

#### 272. Tuberculosis of the Stomach.

E. HJORT (*Norsk Mag. f. Lægevid.*, January, 1928, p. 20), who records a personal case, illustrates the rarity of tuberculosis of the stomach by the following statistics. Of 568 cases of gastric ulcers in Eiselberg's clinic at Vienna in the course of twenty-three years only 3 were of a tuberculous nature. Biernak found only 4 cases of gastric tuberculosis among 12,528 necropsies, and Simmonds only 8 cases among 2,000 necropsies. Hjort's case was that of a woman, aged 47, who suffered from dyspepsia for a year, with occult haemorrhage and normal acid values; resection of the stomach (Moynihan) was performed. No ulcer or tumour was found in the resected portion, but tubercles visible only on microscopic examination were found in the mucosa. The patient had otherwise no clinical symptoms of tuberculosis; the case was therefore an example of primary gastric infection. The incident was of special interest not only as presenting an early form of gastric tuberculosis, but also because this early stage was associated with pronounced dyspepsia without any obvious anatomical basis. The author adds that it is open to question whether the gastric tuberculosis in this case should be regarded as the cause of the dyspepsia, which in the absence of ulcer formation is doubtful, or whether the cause should be sought in an overlooked peptic ulcer in the duodenum or in an ulcer situated high up in the intestine. The presence of perijugal adhesions and the x-ray picture of a dilated stomach of the duodenum is in favour of the last suggestion.

## Therapeutics.

#### 273. Charcoal as a Medicinal Vehicle.

P. BLUM (*Bull. Acad. de Méd.*, January 24th, 1928, p. 119) states that the high adsorptive powers of charcoal, due to its porosity or the presence of impurities, such as traces of iron, lime, or nitrogen, vary so widely, according to its origin and manufacture, that it cannot be employed therapeutically without some degree of selection. It has been widely used, with favourable results, in cases of poisoning. Experiments, however, have shown that in certain conditions charcoal can give up the substances previously adsorbed and thus be utilized as a medicinal vehicle. Using animal charcoal, Blum obtained a preparation of iodine by triturating it with charcoal. Carbets containing 0.01 gram of iodine and 0.5 gram of charcoal were administered at first, but later the amount of iodine was increased to 0.08 gram. These were well tolerated and proved efficacious, the iodine being slowly liberated and exerting, therefore, a more prolonged action on the body. The mixture is now prepared by slightly heating 10 grams of iodine with 30 grams of animal charcoal. After some minutes no trace of free iodine remains; 70 grams of charcoal are then added and intimately mixed, the resulting mixture containing 0.1 gram of iodine per gram. Mercutrial preparations can be similarly made, and experiments are being conducted with bromine, sulphuretted hydrogen, and other substances. Hydrochloric charcoal can easily be prepared by bubbling hydrochloric acid gas through charcoal for ten minutes, stopping the operation for ten minutes, and then renewing it slowly for twenty-five minutes. The charcoal thus prepared should be kept in well-stoppered bottles and its acidity tested from time to time. The charcoal loses a great part of the adsorbed gas during the first five minutes, but then the de-adsorption becomes very slow and lasts for several days. Blum believes that this is a convenient method of administering many gaseous and solid medicaments; that it permits of a molecular therapy by substituting salts for metalloids and metals, and solutions for gases; and that it utilizes the catalysing properties of certain drugs usually given in infinitesimal doses. It is also of advantage in the administration of galenic preparations.

#### 274. Gentian Violet in Dermatology.

A. R. MCFARLAND (*Arch. Derm. and Syph.*, January, 1928, p. 16) records his experience of the clinical use of gentian violet locally in certain pyogenic skin infections and as a prophylactic. Using an approximately 5 per cent. solution in distilled water, with 20 per cent. ethyl alcohol as a solvent and to render the dye more penetrating, rapid improvement resulted in a child suffering from a severe pustular infection of the head and chest, and in an obstinate case of infectious eczematoid dermatitis which had failed to respond to other treatment. In folliculitis and boils improvement followed painting twice daily, but McFarland found the solution of most value in the post-operative treatment of lesions, which had been fulgurated or treated by diathermy, by painting the denuded areas after removal of the burned tissue with a curette. If the skin is kept dry for about twelve hours the dye becomes set and does not wash off; a dry crust forms, which drops off in about a week, the patient suffering but little discomfort or inconvenience. Similar results were obtained in the post-operative treatment of molluscum contagiosum, and one of mycotic infection of the mouth cleared up by its use. For epitheliomata which have been destroyed by diathermy the use of gentian violet is advisable until the granulations begin to form, when a mild stimulating ointment will hasten epithelial proliferation. Results were negative in patients with coecigenic syecosis barbae and epidermophytosis of the feet. The denuded surface to be treated should be as dry as possible, and this may be hastened by swabbing with 1 in 1,000 adrenaline solution. All crusts must first be removed, and no surface should be treated in the presence of an albuminous or mucoid deposit or if there is haemorrhage or oozing. The application should be made with a small applicator wrapped in cotton-wool, since a brush tends to splash the surrounding tissues. The only drawbacks are the colour and the liability to staining after frequent use.

#### 275. Arsenic in Syphilitic Aneurysms.

M. PINARD (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, January 5th, 1928, p. 1711) agrees that specific treatment is useless in cases of non-syphilitic aneurysm, but since it is sometimes difficult to determine the aetiology of the lesion he believes that a test treatment is often successful, and that intensive arsenical treatment is always justifiable in definitely syphilitic cardio-vascular disease. He describes the case of a man, aged 53, who had a large retrosternal aneurysm following syphilis acquired at the age of 18 and untreated. Pinard gave without much benefit four subcutaneous injections of

tropoquinol and twelve of acetylarsan, the patient remaining dyspnoeic and exhausted, and suffering from severe dysphagia. The aneurysm was as large as an orange and had caused extensive absorption of the sternum. In six weeks 6.3 grams of novarsenobenzol were injected intravenously, and the patient improved rapidly. After an interval of three weeks it was decided to give a further series of two daily injections, each of 0.3 gram of novarsenobenzol, at intervals of four days. A second patient had an aneurysm of the right external carotid as large as a pigeon's egg; he had been under the intensive treatment, with intervals, for nearly six years. Over 130 grams of novarsenobenzol had been given. This was well tolerated, and maintained the patient in good health. When the intervals between the series of injections were prolonged, or when the doses were diminished, the serum reaction became positive. Pluad concludes that a less intensive treatment would have been useless. HALLÉ (ibid., p. 1715) doubts, however, whether this intensive treatment with arsenobenzol is necessary to obtain good results. He finds that all treatment often fails, but sometimes the long-continued administration of small doses of mercury and potassium iodide has produced astonishing results in aortic aneurysms. He describes the case of a woman, aged 65, who was treated thus and who survived for several years, dying eventually from heart disease. The aneurysm and peri-aortitis were cured by a very moderate mercurial and iodide treatment. Stead recommends repeated small subcutaneous or intramuscular injections of novarsenobenzol; he considers massive doses dangerous. G. Cansado mentions a case treated in 1898 by injections of 4 mg. of mercuric iodide in oily suspension. After two series, each consisting of ten injections, the symptoms were greatly relieved, but the tumour did not diminish.

#### 276. Treatment of Anorexia in Children.

W. M. BARTLETT (*Amer. Journ. Dis. Child.*, January, 1928, p. 25) has analyzed the consecutive records of 1,471 children presenting themselves during a period of eight months at the out-patient department of a hospital; 349 of them, 24 per cent., had loss of appetite, together with signs of malnutrition. No organic cause could be found in 121 cases; septic tonsils and adenoids were the commonest pathological conditions associated with anorexia and malnutrition, being present in 77 cases. Patients with functional anorexia were treated by one of three methods: (1) the administration of 5 grains of saccharated iron three times a day; (2) half an ounce of cod-liver oil given two or three times a day; (3) fresh calf's liver, broiled beef-steak, and lamb's kidneys as part of the diet at least three times a week. General improvement was noted in each of these groups, but the results were considerably better in the third than in the first and second groups. The author suggests that in fresh liver there is a specific stimulant to the appetite.

## Neurology and Psychology.

#### 277. Impediments of Speech.

DURING a study of fifteen cases of streptosymbolia, or reading disability. S. T. ORTON (*Arch. Neurol. and Psychiat.*, November, 1927, p. 671) noted that three patients stuttered and four others had a peculiar laboured hesitancy in speech. Numerous instances also are recorded of the onset of stuttering when a normally left-handed child is coerced into using the right hand for writing, and of recovery when the use of the left hand is permitted. These cases seem to support the theory that stuttering and streptosymbolia are expressions of confusion in cerebral dominance, and that therefore stuttering would be more closely related to the apraxias than to the ataxias. The act of stuttering is not unlike an ataxia, which has led to the suggestion that the cerebellum may be at fault. No demonstrable cerebellar lesions, however, have been observed in stutterers, and both speech and writing are probably essentially integrative functions of the higher cortical arcs of the dominant hemisphere. Emotional variants may be observed in many stutterers, and further work indicates a marked lack of integrative solidarity—a disintegration—in the stutterer's attempt at speech.

278. L. E. TRAVIS (ibid., p. 673) suggests that the complex peripheral structures serving speech fall into three main functional groups—those of breathing, voice, and articulation. Normal speech displays a harmony in the separate groups and their combinations, while stuttering shows a disharmony in their combination and also within each group. In the investigation six persons with severe forms of stuttering and several normal speakers were studied, and the technique of the experiments is described. The results were that the records of normal speech showed an integration of the various units of the breathing mechanism, which exhibited the follow-

ing characteristics: (1) a fairly close correspondence between thoracic and abdominal breathing; (2) a relatively greater number of laryngeal than breathing movements; (3) a relatively complete independence between vertical movements of the larynx and movements of breathing; (4) an evident rhythm of breathing, of the vertical movements of the larynx, and of the changes in breath pressure; (5) a disproportionate increase in the duration of expiration during speech; and (6) the presentation by the abdomen of small in-and-out movements ranging from five to seven a second. The stutterers showed a disintegration of certain motor speech units which was apparent in the following ways: a complete antagonism between the actions of the thorax and abdomen; a marked synchronism between the movements of the larynx and of the various units of the breathing apparatus; a marked prolongation of inspiration; large vertical movements of the larynx during inspiration; tonic and clonic spasms of the muscles of speech; and a slow abdominal tremor rate.

#### 279. Somatic Conditions in Manic-Depressive Insanity.

T. SONDÉN (*Uppsala Läkartidningen Förhandl.*, September 20th, 1927, p. 25) gives an extensive review of work done in the attempt to discover correlative physical and psychical factors in cases of mania and melancholia. He describes in detail a group of eleven cases of manic-depressive mental disease under his care, and elaborates the numerous clinical investigations performed by him; these included observations of the temperature, pulse rate, blood pressure, respiratory rate, erythrocytes, haemoglobin, leucocytes, albumin content of the serum, blood sugar, non-protein and urea nitrogen, preformed and total creatinin in the blood, the response of the vago-sympathetic nervous system to adrenaline injections, the oculo-cardiac reflex, and Loewi's conjunctival reaction. No parallelism was found between the psychic and somatic conditions, and no definitely abnormal physical factors were discovered; as regards the respiratory rate and non-protein nitrogen the results were completely negative. No clear connexion was found between blood sugar and the psychic condition, but the author states that this result does not contradict the hypothesis of an association between manic-depressive psychosis and diabetes. There seemed to be some numerical increase in the leucocytes, especially neutrophils, during mania as compared with the quiet periods, but the daily variations were considerable and the result of doubtful value. In some cases of mania a rise in the pulse rate was noted during mania periods, especially in the early stages. The blood pressure seemed at times to be definitely higher during periods of both mania and depression than during the quiet periods. Two patients showed increases in the number of red cells during transition stages from quiet to mania and from quiet to depression, but in the other cases no such parallelism was found. The author discusses hypotheses concerning the interrelationship of the endocrine and nervous systems in the psychoses, and suggests that some means of prevention may be found by the employment of therapeutic measures influencing these systems. Numerous charts, tables, and graphs are appended, and a list of references is given at the end of the paper.

#### 280. Friedreich's Ataxia.

G. GIDDINGS (*Journ. Amer. Med. Assoc.*, October 22nd, 1927, p. 1395) reports ten cases of Friedreich's ataxia in one family. Direct inheritance is unusual, but the percentage of cases in a family appears to increase with each generation. In the first generation of this series 4 cases occurred, while in the second generation 6 have developed. Gowers recorded 65 cases in 19 families—an average of 3.42 in each family. In Giddings's series there were six males and four females; their ages ranged from 5 to 42 years. One patient died at the age of 40, another at 30, while 8 are still alive. All developed definite symptoms at the same age—namely, 12. Certain prodromal symptoms, undescribed hitherto, were observed by the parents; in almost every case, from late infancy to the age of 12, a nervous instability, indicated by infantile convulsions, headache, lassitude, or excessive nervousness, preceded the definite onset. Blood and cerebro-spinal fluid Wassermann tests of the patients, parents, and blood relations were invariably negative. There was no familial history of epilepsy or of psychosis in relatives, but some of the parents were closely related. The urine was always normal; two patients had hookworms, and one had a *Taenia nana* infestation, but without secondary anaemia or definite eosinophilia. In some cases severe scoliosis prevented lumbar puncture. Pes cavus, with or without hyperextension of the great toe, was generally present; there was ataxia in 9 cases. The eldest patient, a man aged 42, had been imbecile for six or seven years, and confined to a chair for twenty-five years. Giddings gives details of all the cases, and records the following conclusions: (1) Friedreich's ataxia is not connected with any of the acute exanthemata. (2) When first noted as following these the pre-existent ataxia is aggravated by the patient's weakened

condition. (3) Definite prodromal symptoms may be present for five to seven years before ataxia appears, while disappearance of deep reflexes was an early and constant sign in all but one case. (4) Ocular changes had occurred in 6 cases, but nystagmus was absent. (5) Ataxia developed in 7 patients between 11 and 12 years old. (6) Other congenital defects or stigmata of degeneration occurred, including malformed ears, cardiac abnormalities, and hernia. (7) Scoliosis was constantly present, and appeared to be due to an unconscious effort to control the ataxia. (8) Mental changes were not constant. (9) Laboratory findings were negative. (10) The rate of progress is variable, but all these patients were confined to a chair within five to eleven years after the onset. Treatment is useless.

## Obstetrics and Gynaecology.

### 281. Obstetrical Factors in Neo-natal Intracranial Haemorrhage.

T. C. GREENE (*Boston Med. and Surg. Journ.*, January 12th, 1928, p. 1302) records a study of the incidence, causes, relation to breech extractions, and diagnosis of intracranial haemorrhage in the newly born, based upon 177 consecutive necropsy findings in infants dying before or shortly after birth. Greene concludes that such haemorrhage is the most frequent cause of neo-natal death, since it was present in 55 of the 177 cases; injury to the child's head, especially by sudden trauma, was the most important factor, but disease associated with haemorrhages in the body was sometimes detected. An analysis of the methods of delivery in these 55 cases indicated that intracranial haemorrhage occurs most often in primiparous and operative deliveries, especially breech extractions, though only 5 cases occurred in 258 consecutive breech extractions not preceded by version, and in five of these there was no difficulty in delivery. Since such haemorrhage occurs in a number of simple uncomplicated breech deliveries, and since breech extractions appear to be its commonest cause, the routine use of version and breech extraction is condemned. The author adds that though intracranial haemorrhage is a serious complication, it is not necessarily fatal, and minor breeches of the tentorium and falx can hardly be regarded as a cause of death, though they may be evidence of fatal intracranial pressure transmitted to the medulla. Diagnosis is usually easy, the infants being drowsy and cyanotic, and there may be deviation of the eyes, ptosis, or convulsions. Opisthotonos and a hydrocephalic cry may be present, and the spinal fluid be increased in pressure and blood-stained.

### 282. Pyelonephritis in Pregnancy.

W. S. PUGH (*Med. Journ. and Record*, January 4th, 1928, p. 27) discusses the occurrence and treatment of pyelonephritis in pregnancy. Of 100 apparently normal pregnant women examined from the seventh to the ninth month 80 per cent. showed evidence of uterine retention, mostly right-sided, and it would appear that obstruction with retention is the primary factor in the causation of the disease, bacterial implantation being secondary. A striking feature of the condition, especially when there is marked renal retention, is the high pulse rate, out of proportion to the temperature. Drug treatment was found to avail but little, and continuous drainage through the ureter with as large a catheter as possible is essential. No smaller size than a No. 8 x-ray catheter with several large eyes should be used, since the larger the calibre the better the drainage, with material shortening of the attack. The catheter is left in position in the pelvis of the kidney with its external end draining into a bottle attached to the thigh; if it does not drain properly it should be aspirated and irrigated with normal saline solution. Any initial discomfort can be relieved by mild sedatives or a 1-grain opium suppository. After about three days the smaller catheter may be withdrawn, when it will be found that the patient will take a No. 11 or 13, or even up to No. 18; it is important to use as large a catheter as possible, even performing ureteral meatomy or dilatation if necessary. Concurrently with this treatment copious draughts of water at frequent intervals should be taken. In a series of fifteen cases thus treated fourteen cleared up permanently without the use of any urinary antiseptics.

### 283. Puncture of the Cisterna Magna in Eclampsia and the Pre-eclamptic State.

WIELOCH (*Arch. f. Gynäk.*, November 28th, 1928, p. 296) records his experience of aspiration of cerebro-spinal fluid by suboccipital puncture of the cisterna magna in 10 cases of eclampsia and 45 of the pre-eclamptic condition. The purpose of the procedure is to bring about a diminution in intracranial and intracerebral pressure; as much as 58 cubic centimetres of fluid was abstracted. In 3 only of the 45 pre-eclamptic

cases did a convulsion follow. Two-thirds of the patients showed after the puncture a fall of blood pressure (20 mm. of mercury on the average) and in about one-third of the series a marked diuresis ensued. The pressure of the cerebro-spinal fluid was measured in 12 patients, and on an average was found to be 250 mm. of water, as compared with a normal average value of 150 mm.

## Pathology.

### 284. Etiology of Pernicious Anaemia.

E. LOMBARDI (*Rif. Med.*, January 30th, 1928, p. 98) records experiments on dogs in which he produced an artificial stenosis of the ileum with the following results. In five out of six cases a varying degree of stenosis of the last part of the ileum was produced, and above it a dilatation of the ileum, which in one case reached the size of a second stomach. After the operation the animals showed a characteristic syndrome consisting in progressive emaciation, voracious hunger, and ulceration of the limbs, while the blood showed considerable diminution of the haemoglobin, progressive reduction in the number of the red cells, poikilocytosis, anisocytosis, and sometimes metachromatophilia and leucocytosis. Death followed in eight to nine weeks. In some cases the necropsy showed a reversion of the bone marrow to its embryonic state. These experiments clearly indicate the deleterious action of enterogenous toxins on the blood and general nutrition.

### 285. A Precipitation Test for Syphilis.

REMARKING that one of the chief difficulties of the Kahn precipitation test is in the reading of doubtful and slightly positive reactions, F. B. JOHNSON (*Journ. Lab. and Clin. Med.*, January, 1928, p. 334) describes an adaptation of this test, introduced by Kline and Young, in which the readings are made with a microscope. In this method twelve paraffin rings are made on thoroughly cleansed slides (2 by 3 inches) by dipping a wire loop of 12.5 to 13 mm. diameter into smoking paraffin and touching the slide with it. All the apparatus should be kept at a temperature of between 22° and 27° C., and the air be fairly moist. The serums are heated for half an hour at 56° C., and 0.05 to 0.06 c.c. of each serum is pipetted into the centre of a paraffin ring, positive, negative, and salt controls being also prepared. The antigen, titrated and diluted according to Kahn's method, is most satisfactory when used after the lapse of 10 to 30 minutes. One drop of the antigen dilution is added to each serum with a capillary pipette dropping 0.0075 to 0.0085 c.c. to the drop. The serum and antigen are brought together by a wooden toothpick, further mixing being effected by a rocking circulatory movement of the slide for two or three minutes. The readings are determined in dim light with a microscope. A clear fluid is negative; fine granular clumping is recorded as +, fine flocculation as ++, marked flocculation as +++, and coarse flocculation as +++++. Johnson claims that this method is more simple than the Kahn test, requires less material and time, and gives more easily read results. It is slightly more sensitive than either the Kahn or Wassermann test, and is also adaptable to the globulin concentrated cerebro-spinal fluids.

### 286. Salmonellosis Associated with Hydatid Cysts.

E. L. PEYRE (*Presse Méd.*, January 21st, 1928, p. 85) adds to the bacteriology of hydatid cysts by describing the case of a colonial soldier who went to Indo-China in a transport containing a consignment of parrots, many of which died during the voyage. The patient entered hospital for pleurisy. After much investigation numerous bipolar staining Gram-negative coeco-bacilli were found in pus drawn from the region of the base of the left lung; they were shown to be closely related to *B. paratyphosus* B, but were not agglutinated by the corresponding nor by a human serum, though agglutinated by 1 in 100 serum of the patient himself. The patient's serious condition forbade intervention, but much improvement followed injection of an autogenous vaccine and resection of the eighth rib. The titre of agglutination rose to 1 in 300. About a month later during defaecation a very thick whitish membrane escaped through the wound and suggested a hydatid cyst; this was confirmed by finding *echinococcus* hooklets. Exploration of the wound localized the trouble in the region of the spleen. The patient improved considerably and returned to France. Peyre discusses the diagnosis and localization of hydatid cysts, calling attention to the unreliability of eosinophilia as a diagnostic sign, but emphasizing the value of serum tests. He suggests that the amelioration of the suppuration can be largely attributed to the vaccine treatment. The infection was evidently one of *B. psittacosis* following a hydatid cyst, apparently contracted in Morocco at some previous date.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 287. Oedema due to Hypothyroidism.

P. PAGNIEZ and L. ROUQUES (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, February 23rd, 1928, p. 268) illustrate the occurrence of oedema in hypothyroidism by describing a case of this nature. A woman, aged 32, had noticed for six weeks gradual swelling of the legs and arms which interfered with the movements of the limbs. When first observed the oedema, which was hard, tender, and pitting only on firm pressure, reached to the elbows and almost up to the knees. Pain was present, not only on movement, but at rest also, and there was insomnia from this cause, but x-ray examination revealed no lesion or enlargement of the bones. There had been no remissions since the onset, and no significant history of previous illness was obtained. The extremities were cold and cyanosed, there was no evidence of endocrine disturbance, and complete examination revealed no sign of myxoedema or Graves's disease, nor any further abnormality except a regular tachycardia of 120, which did not yield to rest. Treated by diuretics and calcium chloride the patient made no progress, but on administration of thyroid extract in doses increasing from 0.05 to 0.1 gram daily the swelling and cyanosis gradually disappeared, the oedema resolved, and movements of the limbs became unrestricted. Some months were needed for restoration to the normal, but nine months after starting treatment withdrawal of the drug occasioned relapse. After a year's treatment only slight non-progressive oedema appeared on discontinuance. During this period the pulse rate fell steadily to 80. A study of the literature shows that oedema of this nature occurs principally in thyroid lesions—for example, in Graves's disease—and in certain allied conditions showing permanent tachycardia and tremor without goitre or exophthalmos.

### 288. Carotinaemia.

C. STONER (*Amer. Journ. Med. Sci.*, January, 1928, p. 31), who reports an illustrative case with a review of the literature, states that immediately after the great war German writers described a number of cases by the name of carotinaemia which were obviously due to the high vegetable diet of that period. The cases were most frequently found in children who had been exclusively fed on diets rich in carrots and green vegetables. The chief interest of the condition, which is not accompanied by any symptoms of constitutional disturbance, lies in the fact that it may be confused with true jaundice, the principal difference being the absence of pigmentation of the sclerotics in carotinaemia. The discoloration of the skin, resembling that caused by jaundice, has been shown to be due to so-called carotinoid colouring matters designated lipochromes contained in yolk of egg, fats, and certain vegetables such as carrots, green vegetables, and oranges. Occasionally the colour of the urine is altered. Stoner's case was unusual in that it occurred in a woman, aged 65, who had been living for several months almost exclusively on a diet of vegetables, which included carrots. The skin showed a slight generalized yellowish pigmentation, which was most intense on the palms of the hands and soles of the feet. There was no pruritus, as is the rule in jaundice, and the sclerotics were not icteric. The temperature was normal, and apart from flatulence and constipation, which had been present for years, she had no other symptoms. Examination of the urine was negative, but the test for carotin in the blood was distinctly positive. The issue of the case is not recorded.

### 289. Diphtheria Prophylaxis in Asthmatic Patients.

G. L. WALDBOTT (*Journ. Amer. Med. Assoc.*, January 28th, 1928, p. 290) states that six asthmatic children who had been free from asthmatic symptoms for several months had recurrences of attacks coincidentally with the administration of toxin-antitoxin. In two other children with an allergic family history the first attacks were brought on by administration of toxin-antitoxin. The attacks were of very severe type and did not yield as well to adrenaline as is usually the case in asthma. The skin tests for horse serum were found positive. In all cases eosinophilia was present, and in seven was higher after the injections than before. The author adds that since the benefits of diphtheria immunization are too great to be abandoned in asthmatic persons it is advisable to use Besredka's method of giving small desensitizing doses at frequent intervals.

### 290. Polyneuritis following Mumps.

W. S. COLLENS and M. A. RABINOWITZ (*Arch. Intern. Med.*, January, 1928, p. 61), who record an illustrative case, classify the neurological complications of mumps into (1) meningitis, (2) encephalitis, and (3) neuritis—(a) of the second, sixth, seventh, eighth, eleventh, and twelfth cranial nerves, (b) diffuse polyneuritis, and (c) localized neuritis. Only four cases of diffuse polyneuritis have been described, all by French writers—namely, Joffroy (1886), Revilliod (1896), Gallavardin (1898), and Pitres and Marchand (1922). All the cases of polyneuritis on record presented the quadriplegic syndrome, but they varied in the nature of the cerebral involvement. The motor phenomena always predominated, while the sensory symptoms and signs played a minor part. The common features of all the patients were flaccid paralysis of all the extremities, loss of superficial and deep reflexes, slight or no sensory disorders, and disturbance of the joint and vibratory senses. No deaths followed, and all the patients recovered completely within a month to a year. The present case, which occurred in a man aged 29, after a mild attack of mumps complicated by left orchitis, was unique in that quadriplegia was associated with bilateral facial paralysis and meningitis. Complete recovery ensued within four months.

### 291. Tuberculous Infection in Schools.

J. GOUDSMIT and J. C. VAN DER LOO (*Nederl. Tijdschr. v. Geneesk.*, February 4th, 1928, p. 520), as the result of a study of the literature and their own investigations, have come to the conclusion that in classes which have been exposed for a varying period to infection by a teacher suffering from open tuberculosis a larger number of children develop signs of tuberculosis than might be expected from examination of other groups of children. The authors emphasize this form of infection as being probably of considerable importance, and advocate careful physical examination of school teachers.

## Surgery.

### 292. Diaphragmatic Hernia.

S. W. HARRINGTON (*Archives of Surgery*, January, 1928, Part II, p. 386) reports that an increasing number of cases of diaphragmatic hernia are being detected and that the condition is probably more common than is at present recognized. The embryonic formation of the diaphragm predisposes to herniation at certain sites, and there is a great preponderance of cases on the left side. The types may be classified into the main groups—namely, the traumatic, and the non-traumatic or congenital in origin. The symptoms are often obscure, and indefinite upper abdominal signs demand x-ray examination of the diaphragm. When the symptoms are mild without incarceration of viscera medical treatment may be adopted. Definite attacks of obstruction due to incarceration demand operation. The abdominal approach is usually preferred, and closure of the hernial opening is essential to relieve the symptoms. Paralysis of the diaphragm by phrenic neurectomy assists in closing large apertures. Eight cases are recorded, with no mortality but with recurrence in one case. The best results are said to be obtained in the traumatic variety of hernia.

### 293. Cancer of the Vermiform Appendix.

M. PÉRAIRE (*Bull. et Mém. Soc. de Chir. de Paris*, December 16th, 1927, p. 833) remarks that cancer of the appendix is only discovered either at a necropsy or during the course of an operation. He reports a case in which it was found while operating to remove a parovarian cyst in a patient aged 30. This condition has been found at all ages, but more frequently in females. The growth in the appendix is usually small, and large tumours are exceptional; its consistence is hard, and it is usually found at the tip of the organ. The glands are not as a rule involved, and metastases do not appear to occur. The condition gives rise to no special symptoms, apart from those of chronic appendicitis. It is not unlikely that the carcinomatous condition may follow on or be secondary to an old attack of acute appendicitis where the lumen of the organ has become obliterated. Contrary to what is found in other cases of cancer, the prognosis is good, and appendicectomy removes all danger of any recurrence. The treatment is removal of the appendix and its mesoappendix. The disease is histologically serious, but clinically benign.

## 294. Thrombo-angitis Obliterans.

M. LETULLE, J. MARCHAK, and G. BOYER (*Presse Méd.*, February 15th, 1928, p. 193) base their account of this disease upon a series of twenty-eight patients under their observation in Paris. Clinically they recognize three periods. (1) The insidious beginning is often found in the superficial veins of the limbs; the arteries are sometimes not affected for several years. Phlebitis always precedes true gangrenous changes. Sometimes veins, even when varicose, are completely blocked, and absorbed. The hair of the limbs comes out, and in slight cases swelling and heaviness of the feet are observed. There are also small tender inflammatory nodules in or below the skin. This stage of the disease may pass almost unnoticed by the patient. (2) After a period varying from two to seven years the second stage begins by the patient being seized one day when walking by a sudden pain, which feels like a sprain of the plantar arch or toe-joint. After a time his legs get weaker and the distance he can walk diminishes. His feet cannot bear the heat of the bedclothes and a slight jar brings on intolerable pain. He cannot sleep lying down and generally consults a doctor at this stage. The feet are rather dry, and pain is increased by warmth. Exercise produces vasoconstriction. Arterial examination by oscillometry is usually positive. The leucocyte count was 10,000 to 15,000 per c.mm. in half the cases, and the blood cholesterol figure was raised. The condition is easily mistaken for gout, rheumatism, or gonococcal arthritis. (3) The third period often begins during cold weather. The former symptoms are aggravated. The painful attacks are more frequent, the limb is blanched, and a little vesicle forms on the toe. It ulcerates, does not heal, and multiplies, becoming acutely painful. Morphine is necessary, and finally in most cases amputation. As regards treatment, sodium citrate, insulin, and sodium nitrite have been tried, the latter being successful in five cases. Out of 21 cases 13 thus treated were able to resume their work. Amputation when necessary should be done at the lower third of the limb. (Buerger's disease) is characterized by a definite lesion of thrombo-angitis—the lumen of the vessel being almost entirely obliterated by an organized thrombus containing many giant cell systems. Seven plates drawn from sections of vessels in amputation material show in detail the characteristic lesions found in the disease. The authors conclude by stating that on both clinical and histo-pathological grounds it is an entity due to some specific but undetermined cause resembling leprosy, tuberculosis, and syphilis.

293. E. V. ALLEN and H. W. MEYERDING (*Surg., Gynecol. and Obstet.*, February, 1928, p. 260) discuss the surgical procedure in thrombo-angitis obliterans with a report of 45 cases. Fatigue or claudication pain after exercise, relieved by rest, are early symptoms, followed by burning or aching in the digits unrelated to exercise and later becoming unbearable and only relieved by amputation. The earliest objective sign is a bluish-red discoloration with cold extremities, diminished pulsation, and followed by gangrene. A study of the cases showed that incision of toes or removal of nails should not be performed, and that amputation of toes is successful only in selected cases. In approximately 80 per cent. amputation below the knee is successful provided that medical post-operative measures, such as radiant heat, can be employed to increase the blood supply to the stump. Amputation above the knee should only be undertaken in cases in which infection or trophic changes are very extensive, and for those patients who are unwilling to risk a 20 per cent. chance of failure of amputation at a lower level. Procedure in each case has to be decided on its merits, it being remembered that function in many cases can be re-established by medical treatment. Cases of gangrene of the toes only should be treated medically provided that the pain can be relieved and economic conditions do not call for surgical intervention.

## 295. Preservation of the Limbs after High Ligation of the Vessels.

O. FRISCH (*Zentralbl. f. Chir.*, January 21st, 1928, p. 141) does not agree with H. Hartleb that the continued vitality of a limb after ligation of the main blood vessels is very doubtful. In 1916 Frisch had two cases of ligation of the femoral artery; these indicated that, as a rule, the limb is not endangered by ligation. He mentions that in the Russo-Japanese war ligation of the great vessels yielded very good results. In the Balkan war Frisch ligatured fifteen aneurysms: of these, five were of the femoral artery, one of the axillary artery, and one of the subclavian, and in no instance was there any interference with the nutrition of the limb. Frisch adds that many other surgeons have had similar successes; usually the collateral circulation was established quickly, and the continued vitality of the limb was not endangered.

## Therapeutics.

## 297. Glukhormont in Diabetes.

F. RATHERY and P. MOLLANET (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 16th, 1928, p. 203) have investigated the therapeutic action of glukhormont in diabetes. Two methods of administration have been tried, each of them on two cases of diabetes mellitus with wasting. To the first two patients glukhormont was given in doses increasing from one to two tablets (30 grams each) after food three times a day. There followed at once slight reduction of glycosuria, acetoneuria, and the blood sugar, with a marked falling off of beta-oxybutyric acid in the urine. In the second group of cases glukhormont was given in conjunction with insulin. With a constant dose of insulin there resulted a decided fall of sugar in the blood and urine and in the acetone bodies, but there was increased excretion of beta-oxybutyric acid. On the other hand, it was found that if the usual dose of insulin was reduced during the administration severe acidosis and coma resulted. The authors conclude that neither synthalin nor glukhormont can compare in efficacy with insulin. Glukhormont is found to have the power of decreasing glycosuria and hypoglycaemia, but pronounced individual variations occur precluding the determination of sugar and glukhormont equivalence. A marked action in reducing ketosis is observed, but this and the other properties of the drug usually become apparent after a certain delay. Some patients show great intolerance to both synthalin and glukhormont. It is considered that equilibration by diet should always be attempted, and that if this fails synthalin or glukhormont may replace insulin by virtue of its easy administration, but only under close supervision; injections of insulin should be renewed if the blood sugar or acetone bodies tend to increase. The authors add that there is evidence to suggest that synthalin and glukhormont are identical in composition. (See Dale and Dudley, *British Medical Journal*, December 3rd, 1927, p. 1027).

## 298. Treatment of Otitic Sepsis.

H. I. LILLIE (*Arch. of Otolaryngol.*, January, 1928, p. 30) records his results in twelve cases of septicaemia following mastoiditis and lateral sinus infection. Good results having followed transfusion in septicaemia, he resolved to use it in lateral sinus sepsis, and particularly in the case of patients who were in a serious physical condition before operation, or who did not appear to be recovering subsequently. In many cases he transfused blood before the operation with very good results. When a blood culture showed an actual blood infection a solution of germicidal dye was added to the blood at the transfusion or was given separately. Mercurochrome-220 was the dye used; this has been reported as having high bactericidal properties, especially for *Staphylococcus coli*, while gentian-violet is said to be specific for Gram-positive cocci, but is more difficult to prepare and to standardize than mercurochrome. The optimum dose of the dye was found to be 5 mg. for each kilogram of body weight, and the best results were obtained by adding it to the transfused blood. The combined transfusion, whether pre-operative or post-operative, had the effect of reducing the temperature and pulse rate considerably and lessened the operative shock. Blood transfusion was found also to shorten convalescence and add to the recuperative powers, the dye being entirely a curative measure. Lillie insists that transfusion and injection of the dye cannot in any way supplant operative measures, but are auxiliary.

## 299. Serum Therapy in Scarlet Fever.

B. JOHAN (*Monats. f. Kinderheilk.*, December, 1927, p. 536) has observed 25,000 children on whom the Dick test was made. He finds that on repeating the test conflicting results appear in some cases, which he thinks may be due to faulty technique or may mean a real change in immunity. The majority of Dick-positive patients were between 2 and 4 years old, while most cases of scarlatina occur between 5 and 9 years of age; Johan attributes this to the greater risks of infection at the later period. In spite of such variation he considers the Dick test sufficiently reliable to justify further investigation. He states that in Hungary more than 25,000 children were immunized by the Dick method; of these, no child who was Dick-negative at the time of exposure has become infected by scarlet fever. In a few cases children who were very strongly positive but who received a small injection remained negative for only a short time, and eventually became infected. In his opinion more work is needed to settle the dosage necessary for acquiring permanent immunity. Therapeutically two varieties of serum are used, one of which is prepared from convalescents and the other from horses treated with bacemolytic streptococci from scarlatina cases. Johan has found the Dick unit unsatisfactory and has elaborated another method, taking the size

of the reaction as standard and defining a scarlatina antitoxin unit. He has treated 144 patients with horse serum and 148 with convalescent serum; he compared the results with those in 1,838 cases treated without serum, which was given only when the infection was severe. Convalescent serum injected intravenously proved the most effective, with a mortality of 4.5 per cent.; intravenous injections of horse serum gave 6.9 per cent.; and untreated cases 20.2 per cent. Intravenous injection was found to be more effective than intramuscular. The earlier the serum was given the better the result; if injected after the fifth day the mortality was doubled. The best strength for a moderately severe case was 4,000 units, the mortality being three times less than if the dose was only 1,500 units. Patients reacting well to serum were found to be less subject to nephritis and otitis.

### 303. Treatment of Bronchial Asthma.

H. B. WILMER (*Arch. Phys. Therapy*, January, 1928, p. 18) maintains that the infra-red and ultra-violet rays should be used in all cases of bacterial sensitivity as an adjunct to bacteriotherapy. The treatment is indicated in all children suffering from asthma, no matter what the cause, who are definitely anaemic and show evidence of rickets; in all patients whose living conditions are poor with inadequacy of sunlight; and in adults with a dry cough and very tenacious sputum. Of 20 children aged from 2 to 10 years, 14 were relieved, 3 improved, and 3 showed no benefit from this treatment; of 12 patients aged from 10 to 21, 6 were relieved, 2 were improved, and 4 were not benefited; and of 50 between 21 and 72 years of age, 30 were relieved, 8 improved, and 12 were not benefited. Most of them had been unsuccessfully treated by various methods before radiation was employed.

## Dermatology.

### 301. Gold Treatment in Psoriasis.

N. TOOMEY (*Urol. and Cutan. Rev.*, December, 1927, p. 747), who records five illustrative cases in adults, states that for the last seven years he has treated selected cases of psoriasis by colloidal gold, which may be given by the mouth or, in obstinate cases, intravenously. No untoward effects were observed. The preparation originally employed for intravenous injection and most cases of oral medication was made from gold chloride according to the method used for making the Lango spinal fluid test reagent. Recently Toomey has used for oral administration a stronger suspension made from chemically pure metallic gold treated with bromides and from gold tribromide. The dose varies from 1 drachm (4 c.cm.) three times a day to a tablespoonful (16 c.cm.) two or three times a day. The author reports that the drug should be administered on an empty stomach, and a glass of water should be taken immediately afterwards. Intravenous injections are given twice a week, beginning with 5 c.cm. and increasing the dose to 10 c.cm. Improvement, the rate of which varies greatly, is generally noted in the following sequence: loss of sensations of tenderness and burning, cessation of itching, less congestion of the lesions, and diminution in acanthosis and scaling. There are said to be no contraindications to the treatment apart from albuminuria. Toomey adds that colloidal gold is not expensive, or unpleasant to take. Though not an indispensable or specific remedy, he finds that, if taken for a sufficient time, it will usually produce as lasting a cure as can be effected by any other method of treatment.

### 302. Diseases of the Skin in Asthma.

K. H. BAAGÖE (*Acta Med. Scand.*, vol. lxxvii, Fasc. III, p. 189, 1927) has performed cutaneous tests in 120 out of 124 cases of asthma (92 children, 32 adults). Among these 124 patients there were as many as 74 who had had some disease of the skin or were still suffering from it. Prurigo occurred in 36 cases, urticaria in 34, pruritus in 14, paresthesia in 2, local oedema in 6, and certain other skin diseases in 4. The cutaneous tests involved the use of such substances as feathers, hairs, foodstuffs, and pollen, and among 70 patients with diseases of the skin there were 57 giving a positive cutaneous reaction. Among 50 asthmatics with no skin affections and submitted to skin tests there were 30 who gave a positive reaction. The author admits that as no control material was investigated the claim could not be made with certainty that the above-mentioned skin diseases were more common in asthmatics than in persons not subject to asthma. But he adds that there seems hardly any reason to doubt the existence of a relationship between the skin affection and the asthma in those cases in which the two conditions developed simultaneously. With regard to the character of the skin diseases observed, he notes the exist-

ence of several characteristics common to them all. Thus they appeared in paroxysms and were associated with hyperaemia, oedema, and itching. For this reason, and because most, perhaps all, of these cases of skin disease were due to an idiosyncrasy, Baagöe follows the suggestion of certain American authors in including these diseases in a common group, with the title "Idiosyncratic or allergic diseases of the skin."

### 303.

#### Creeping Disease.

G. R. HAMILTON and E. W. FERGUSON (*Med. Journ. of Australia*, December 24th, 1927, p. 875) record a case of larva migrans in a girl, aged 3, who had lived for two and a half months in New Guinea. She spent a week at Samarai, where it rained all the time and she went barefooted, and then sailed for Sydney. On the second day at sea a small spot like a flea-bite was noticed on the middle toe of the right foot, and two days later similar spots appeared on the left sole. Each day following a ridge formed along the line of small blisters until, eight days later, it had travelled across the left sole, and the ridge on the right too had extended down one side of the toe and up the other. The track was always most red at its advancing end, while the other end slowly faded; there was intense itching at both sites. Both areas were excised widely and Thiersch grafts applied, which took well; from the time of operation all itching ceased. No parasite could be found. Creeping myiasis has been attributed to (1) the larvae of oestrid flies, (2) nematode larvae, (3) mites, and (4) inanimate objects such as horsehair. Of these it is possible that a nematode infection by *uncinostoma* and stronglylodes larvae may have been responsible for this infection, since New Guinea is heavily infested with hook-worm. Previous references to creeping disease have appeared in our *Epitome* columns (1926, vol. II, paras. 18 and 19, and 1927, vol. I, para. 529).

### 304.

#### Acröderrmatitis Perstans.

S. E. DORE (*Brit. Journ. Derm. and Syph.*, January, 1928, p. 12) records five cases of *acroderrmatitis perstans*—a rare, chronic, vesicular, and pustular eruption of mild, localized, but persistent character, affecting the palms of the hands, the fingers, and the soles of the feet. The condition is distinct from and not related to dysidrosis, eczema, dermatitis, or ringworm, and the nails are not necessarily affected. In the cases reported the eruption was limited almost entirely to the thenar and hypothenar eminences and palms, and the soles were rarely affected. The diagnosis from dysidrosis depends mainly upon its distribution, chronicity, resistance to treatment, and the destructive character of the lesions, which first appear as phlyctenular pustules resembling "small lakes of pus," with but little surrounding inflammatory reaction. Ringworm was excluded by microscopical examination and cultures. There was no history of whitlow or of any septic infection, and no evidence of a venous or vascular causation; the condition may remain localized and persistent without giving rise to any more serious sequelae. Various methods of treatment were adopted. In one case crude coal-tar in Lasar's paste was beneficial and prevented the eruption of fresh pustules for several months after x-ray, nitro-violet light, and ionization, and the evacuation of the pus, with insertion of pure carbolic acid, had failed. In another case affecting the soles of the feet treatment with iodine oil and x-rays caused some improvement, but fresh pustules developed when the x-rays were discontinued. Another patient was benefited by repeated ionization, but in some of the cases no treatment was permanently successful.

## Obstetrics and Gynaecology.

### 305.

#### Fibroids in Pregnancy.

J. O. POLAK (*Surg., Gynecol. and Obstet.*, January, 1928, p. 21) discusses the influence of fibroids on pregnancy and labour. Not only is the development of the pregnant uterus influenced by fibroids, but the pregnancy affects the fibroids by increasing their nutrition so that they tend to enlarge in the lines of least resistance. Their effect upon any particular pregnancy will be determined by their site. Treatment resolves itself into determining whether the patient's life will be endangered by allowing the growth to remain, and estimating the effect of its removal upon the continuation of the pregnancy, but experience goes to show that women with uterine myomata usually go through pregnancies with but little difficulty, so that the necessity for therapeutic abortion rarely occurs. In the majority of cases there will be no necessity for surgical intervention unless the tumour by its position or degeneration seriously endangers the patient. Polak advises delaying any operative intervention until the child is viable, while endeavouring to prevent abortion by rest at the

expected menstrual periods, and by the daily adoption of the knee-chest posture in order to prevent impaction of the tumour mass and uterus in the pelvis and to relieve engorgement. When the tumour blocks the birth passage Polak thinks that no attempt should be made to displace it manually because of the risk of injury to the mother, child, and tumour; if the knee-chest position does not lift the tumour out, section followed by enucleation or hysterectomy should be performed. Many fibroids, especially intramural growths, diminish in size and disappear during involution, but an emergency operation during the puerperium may become necessary should injury to the tumour in the course of labour be followed by necrosis or infection. Polak adds that during the puerperium surgical intervention is only indicated in the pedunculate, subserous, and intrauterine polypoid growths, while radium and x rays have no place in the treatment of haemorrhages from them during this period.

### 306. Radium Treatment in Pregnancy complicated by Carcinoma.

H. POUEY (*Bull. Soc. d'Obstet. et de Gynéc.,* December, 1927, p. 702) reports a case of cervical carcinoma in a pregnant woman; radium treatment was followed by a normal *accouchement*. A multipara, aged 34, and six and a half months pregnant, had on the posterior cervical lip an ulcerating haemorrhagic tumour, which proved to be a spino-cellular epithelioma. Radium was applied on three consecutive days, followed by a day's rest. Treatment was then continued in smaller doses, and finally stopped in about six weeks. A month later the tumour had disappeared. The pregnancy pursued a normal course, and eighteen days before the supposed full term the patient was delivered of a healthy, well-developed child. Six weeks after confinement a final application of radium was made. Two months later the patient showed signs of a rectal radium-necrosis, which, however, yielded to treatment with alkaline enemas. Nearly four years later both mother and child were well, and the cure seemed to be permanent, no trace of cancer being found. Pouey draws attention to the perfect tolerance of the pregnant uterus to the radium, to the natural delivery without laceration of the cervix, and to the normal post-partum period. He believes that the rectal necrosis could have been avoided by the use of a supplementary lead filter covered with rubber.

### 307. Lipiodol in Gynaecology.

C. BÉCLÈRE (*Bruxelles-Médical*, January 8th, 1928, p. 319) comments on the valuable results obtained in gynaecological diagnosis by means of injections of lipiodol into the uterine cavity and tubes; the only contraindication is pregnancy or acute febrile conditions. He thinks it better to inject the solution through soft catheters and at a pressure not more than 30 cm. Hg, taking care that the fluid does not escape into the vagina. No bad results have been observed after this practice, and by its means it is possible to see the size and shape of the uterine cavity, ascertain the permeability or otherwise of the tubes, detect where any obstruction is situated, determine the shape and position of the uterus, and gather useful information as to the site of fibromas if present. In cases of metrorrhagia indications of irregularities in the mucosa can be made out, and in sterility associated with tube disease valuable data as to the best method of procedure can be ascertained. It is advisable to take stereoscopic pictures when possible. The author bases his conclusions on an experience of over a hundred cases, for the most part verified by operation.

## Pathology.

### 308. Intestinal Absorption.

K. HOSOI, W. C. ALVAREZ, and F. C. MANN (*Arch. Intern. Med.*, January 15th, 1928, p. 112) conducted a series of intestinal absorption experiments upon dogs in order to discover a diet giving the least possible residue and likely to be useful in the treatment of diarrhoea or after rectal or anal operations. By an end-to-end anastomosis of the ileum and rectum a fistula of the terminal ileum was practically obtained, yet retaining a normal anus and sphincter, rendering it easier for collecting faeces and the care of the animal. Fasting residues, faecal characteristics with different diets, and the rate of passage of protein, carbohydrates, fats, fruits, liquids, sugar, and milk were studied, as also the influence of milk upon the digestion of other foods, the amount of residue with different foods, and the influence of the quantity given. From these observations it is concluded that the best basis for a low residue diet is lean meat, with possibly rice, hard-boiled eggs, sugars (except lactose), and small amounts of fruit juices, tea, and coffee; the highest degree of absorption was obtained by giving small quantities often and keeping the diet fairly dry.

The fact that milk leaves a large residue in the terminal ileum shows that this food should not be given when it is desired to prevent bowel movements. The authors emphasize the fact that milk should be avoided when it is desired to allow the digestive tract to rest. They think that it should be forbidden in diarrhoea, since their experience is that it had a bad effect in many such patients, who promptly improve when given meat alone or with a little pure starch and sugar. Their results agree closely with those obtained in a dog and man with the colon intact, thus showing that the colon absorbs little besides water. Contradicting the general belief in the nourishing properties of a raw egg, attention is called to the indigestibility of raw egg albumen and the resulting large moist residue. The highest percentage of moist residue was found with raw banana, which sometimes gave rise to stools larger than the original meal, as was also the case with prunes and baked potato. Large moist residues were obtained after giving lard, butter, Swiss cheese, apple, milk and bread.

### 309. Bacteriology of the Common Cold.

KATHERINE C. MILLS, G. S. SHIBLEY, and A. R. DOCK (*Journ. Exper. Med.*, February, 1928, p. 193) have studied the incidence of Gram-negative filter-passing anaerobic bacteria in the nasopharynx of healthy persons and of patients with colds. The general procedure was to wash out the nasopharynx with broth, filter the washings through a Berkefeld candle, and inoculate Smith-Noguchii medium, fresh rabbit blood-agar plates, and rabbit's blood broth with the filtrate. These were then incubated anaerobically, and the fluid cultures plated after a week. During the winter of 1925-26 five healthy normal persons were watched over a period of five months; during the winter of 1926-27 three normal persons were studied. Fresh examinations were made when these persons developed colds. In addition, other patients with colds were examined on single occasions only. The incidence of the Gram-negative filter-passing anaerobes in the normal was 78.6 per cent. during the winter of 1925-26, and 70 per cent. during that of 1926-27. In patients with colds, on the other hand, the incidence of these organisms during these two winters was 48.5 and 44.4 per cent. respectively. Taking into consideration the difficulties encountered in the cultivation of these organisms, the authors regard it as probable that they are nearly always present in the upper respiratory tract of healthy persons, but that there is a definite decrease in their incidence during colds. Careful examination of twenty-nine strains showed that they could be distributed roughly into three groups on a morphological, cultural, and biochemical basis; serologically the strains exhibited considerable heterogeneity, and displayed no relation to their source of origin. The authors conclude that these organisms constitute part of the normal flora of the upper respiratory tract, and probably bear no relation etiologically to the common cold.

### 310. Immunization against Diphtheria.

G. RAMON (*C. R. Soc. de Biologie*, February 10th, 1928, p. 351) has investigated different methods of producing experimental immunity to diphtheria in guinea-pigs and horses, comparing an anatoxin-antitoxin flocculate with the simple anatoxin. The flocculate, which was the result of mixing a given quantity of anatoxin with less than the full neutralizing dose of antitoxin, was dissolved in distilled water or suspended in saline; it was used either unheated or heated to 70° C. for forty-five minutes. In the first series of experiments six groups of six guinea-pigs were used; each received two doses of the antigen at an interval of three weeks; the degree of immunity resulting was tested a fortnight after the second injection by inoculation with apparently increasing doses of toxin. The results were quite clear; the four groups which received flocculate, heated or unheated, dissolved in distilled water or suspended in saline, resisted from 20 to 50 minimal lethal doses of toxin; the two which received an equivalent amount of anatoxin, heated or unheated, resisted from 500 to 1,000 doses of toxin. In the second series of experiments three groups of guinea-pigs were used; a single injection of the antigen was given, corresponding to 10 c.c. of anatoxin (five times the dose used in the first series), and the guinea-pigs were tested five weeks later. The animals which received the flocculate resisted only 5 minimal lethal doses of toxin, whereas those injected with the pure anatoxin resisted 200. A final experiment was made on horses. Four groups of five horses were used; each received three doses of the antigen at weekly intervals; the antitoxin content of their serum was tested a week after the last injection. Those treated with a saline suspension of flocculate, heated and unheated, had a titre of 26 and 30 units respectively; those injected with anatoxin, heated and unheated, had a titre of 125 and 140 units respectively. The authors conclude that anatoxin is undoubtedly much superior to an anatoxin-antitoxin flocculate in producing experimental antitoxin immunity in animals.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

311.

### Cardiac Neurosis.

F. A. WILLIUS (*Minnesota Med.*, February, 1928, p. 102) discusses the problem of functional disturbances of the heart, mainly from the neurogenic standpoint. Knowledge of the vital importance of the cardiac activity, and the frequent references in literature and the drama, direct the attention of the individual to the heart from childhood onward. This is one of the factors which play a part in the production of cardiac neurosis; others are hereditary disposition to emotional instability, and a condition of depleted nervous reserve in which fitness of judgement is blunted. Some event such as abnormal physical effort produces augmented cardiac action and a sense of palpitation which makes an undue impression upon the distorted perceptive faculty. The patient worries and becomes sleepless; the threshold of tachycardia and palpitation is lowered so that a vicious circle is established. The occurrence of extra-systoles or of paroxysmal nodal tachycardia may produce the same neuroses by the same mechanism. Willius urges the importance in every case of settling rapidly the question of the presence or absence of organic disease in order to avoid cardiac neurosis. He thinks there is no good ground for the belief that functional disturbances depend upon unrecognized pathological conditions; cardiac neurosis is therefore a definite clinical entity. The possibility of neurosis superimposed on cardiac disease is considered, and a free discussion with the patient and relatives is advised; explanation of the necessity for certain restrictions will eliminate fear and introspection. The judicious use of bromide is helpful in many of these cases, and quinine often diminishes the frequency and severity of attacks of functional paroxysmal tachycardia.

312.

### Exanthema Subitum.

A. P. BRAUNSTEIN (*Jahrb. f. Kinderheilk.*, January, 1928, p. 386) reviews the literature (see *Epitome*, December 19th, 1925, para. 558; February 27th, 1926, para. 229; December 18th, 1926, para. 562; November 12th, 1927, para. 431) and records his observations on five cases which he had recently seen at Charkov, thus giving the first description of the occurrence of this disease in Russia. The patients were aged from 7 to 19 months; three of them were boys and two girls. In all but one the temperature kept high for three to three and a half days, reaching a maximum of 103.6°. The eruption, which was morbilliform, appeared on the fourth day simultaneously with the fall of temperature, and disappeared in two days without leaving any trace. It extended over the whole body, but was most pronounced on the trunk, especially the back. No complications or sequelae were observed. The blood picture was characterized by a leucopenia, relative lymphocytosis, and diminution of the polymorphonuclear leucocytes. In short, the clinical picture of Braunstein's cases closely corresponded with the description of the American writers such as Zahorsky, Veeder, and Hempelmann, as well as with that of Glauzmann and von Bokay. Further investigations are needed to determine whether exanthema subitum is an independent nosological entity or not.

313.

### Goitre in Adolescence.

P. STOCKS and A. V. STOCKS (*Biometrika*, December, 1927, p. 292) have made an anthropometrical study of the relation between the size of the thyroid gland and the physical and mental development in adolescence. They find that the measurement of the maximum breadth of the gland is the most reliable index to its actual size. The authors report the statistical results of clinical examinations conducted in various parts of this country, and they find that the prevalence of goitre increases with age to a maximum in boys of about 13 to 14 years old, and in girls of about 17 to 18, when it declines. Where goitre is not endemic the gland hardly changes between the ages of 10½ and 13½, this flattening of the growth curve just before puberty being unique among physical measurements so far undertaken. In girls a rapid development of the gland occurs between the ages of 13½ and 15, which is doubtless associated with the onset of menstruation. There appears to be, in boys, no evidence of any relation between the size of the gland and the physical development, size of the head, the rate of growth, or the strength of the grip. In girls, however, there is a significant positive association with the height and weight, the rate of growth, the grip,

and the systolic and diastolic pressures, but none with the pulse pressure and rate, the colour of the hair and eyes, or proficiency in school work. The authors attach importance to the correspondence between growth curves of the thyroid and of the diastolic pressure, and add that long-continued general development in excess of the average rate seems to favour the appearance of large goitres; while slow development, followed by temporary rapid growth, is associated with small enlargements. They think that these complex relations in girls are capable of being explained on the theory of iodine deprivation, for which theory they afford indirectly an additional proof. They are opposed to the infective theory unless it is assumed that the agent of infection acts by preventing the proper absorption of iodine.

314.

### Alkalis and Renal Injury.

E. J. STIEGLOTZ (*Arch. Intern. Med.*, January, 1928, p. 10) remarks that alkalinization of the urine by administration of alkalis greatly increases the renal cellular acidity. This reversal of intracellular reaction is undoubtedly physiologically irritating, and thereby often causes a renal diuresis. The alkalosis which may be produced by long-continued or excessive administration of alkalis causes distinct renal irritation and occasionally a true nephrosis. This probably does not occur more frequently because of the tremendous reserve of renal structure and physiological efforts at compensation. In the author's view the administration of large doses of alkalis is therefore contraindicated, especially in the presence of pre-existing renal disease.

315.

### Diphtheria after Active Immunization.

P. S. RHODES (*Journ. Amer. Med. Assoc.*, January 28th, 1928, p. 254), who records fourteen cases of clinical diphtheria in nurses who had received three doses of toxin-antitoxin, states that the persistence of positive Schick tests in 67.2 per cent. of cases and the occurrence of clinical diphtheria in cases which had been given toxin-antitoxin is a not infrequent occurrence. The explanation of this disappointing result is that the commercial preparation used is not sufficiently potent. It is therefore necessary that Schick tests should be repeated three months after the last dose of toxin-antitoxin, and that more immunizing doses should be given when they are indicated. Moreover, when large numbers of toxin-antitoxin immunizations are required it is advisable to make tests for potency on the particular toxin-antitoxin to be used before the work is undertaken.

## Surgery.

316.

### Osteomyelitis of the Scapula.

MASSABEAU, A. GUIBAL, J. CHARDONNEAU, and L. MARCHAND (*Arch. Soc. Sci. Méd. et Biol. de Montpellier*, February, 1928, p. 55) describe a case of acute osteomyelitis of the scapula, and point out that the shape and position of this bone make the diagnosis a difficult problem. The patient was a boy aged 14. When first seen the shoulder on the affected side was kept immobile and the respiratory movements were diminished. Palpation produced pain all over the scapular region, but there were no evident signs of inflammation. The next day a swelling appeared between the scapula and the spine, and an exploratory puncture showed the presence of pus. A diagnosis of empyema was made. An operation disclosed that the pus was coming from the scapula itself, the periosteum of which was stopped up. The bone was drained and the patient made a satisfactory recovery. The authors add that the chief diagnostic sign in this condition is localized pain along the axillary border of the scapula. The best incision is one along the vertebral border, which gives access to all the bone. The condition is rare and causes much difficulty in diagnosis.

317.

### Treatment of Cholecystitis.

BACQUELAINE (*Le Scalpel*, February 25th, 1928, p. 197) states that in cholecystitis, in addition to cholecystotomy, often insufficient, and cholecystectomy, often too radical, there is another possible procedure, which he terms "biliary deviation"; he reports thirteen cases in which this operation was performed, in twelve by a cholecysto-gastrostomy, and in one by a cholecysto-colostomy, the results in all being excellent. In seven of these cases the gall-bladders were enlarged, with healthy, tense walls; the thickened contents showed no signs

of infection, and no adhesions were present. The affection seemed essentially mechanical, the vesicular retention following a diminished permeability of the common bile duct and the bile reaching the duodenum by a sort of overflowing. In four of the cases lithiasis was present; one was complicated by a neoplasm and one by gastric ulcer. In the latter the excess of hydrochloric acid was neutralized by conveying the alkaline bile directly into the stomach. Bachelard contends that if the bile cannot reach the intestine freely it is logical to conduct it there by deviation, and he maintains that from a technical point of view these operations are simple and benign. Local anaesthesia suffices in the majority of cases. The organs involved lie immediately under the peritoneum in contact with one another; there is no pulling of the organs, no deep manipulation, no shock; tamponing and drainage is unnecessary, and the operative procedures are simple. The operation is indicated in cases of chronic cholecystitis without calculi, and of cholelithiasis where the walls are sufficiently healthy to permit suturing. The advantages over cholecystectomy are its greater benignity and the absence of subsequent adhesions. Moreover, in cases where cholecystectomy fails, no further surgical intervention is possible, while after failure in cholecysto-gastrostomy the organs can be replaced in their original position and such other operation performed as is deemed advisable.

### 318. Tumours of the Pineal Gland.

K. O. HALDEMAN (*Arch. Neurol. and Psychiat.*, November, 1927, p. 724) describes two cases of tumour of the pineal gland, and also gives a tabulated summary of the microscopic findings, symptoms, and sex and age incidence of 113 additional recorded cases. In each of the two present cases, both females, the tumour proved to be a glioma, and in one a syringomyelic cavity was found. The association of such cavities with intracranial tumours is rare, and is due, according to Langhans and Kronthal, to a venous stasis in the cord, the tumour forcing the cerebrospinal fluid into the foramen magnum with compression of the vertebral veins, the resulting oedema and stasis favouring distension of the central canal, hydromyelia, and disintegration of the grey matter of the cord. The symptoms observed in cases of tumours of the pineal gland may be grouped as follows: (1) General symptoms of intracranial pressure: headache (especially occipital), vomiting, choked disc, mental apathy, somnolence, clonic spasms, and incontinence of urine and faeces. (2) Localizing symptoms: ocular palsies, rigid dilated pupils, nystagmus, blindness, deafness, cerebellar symptoms (ataxia, adiadochokinesis), peduncular symptoms (monoplegia, oculomotor paralysis), pontobulbar symptoms (disturbances of speech and swallowing), and disturbances of hypothalamic sympathetic nerve centres (exophthalmos, tachycardia, etc.). (3) Symptoms referable to the gland: many young patients show a precocious sexual development and adiposity or general overgrowth, which with symptoms of internal hydrocephalus constitute the syndrome designated by Pellizzi as macrogenitosomia praecox. An analysis of all the reported cases shows that the eye symptoms are important in localizing pineal tumours, the most significant being paralysis of upward movement, diplopia, abducens paralysis, nystagmus, ptosis, and absence of the pupillary light reflex. Of 102 cases in which the sex was reported 78 were males, and the greatest age incidence was during the second decade. Surgical removal of these tumours, while difficult and resulting fatally in most cases, has been advocated by Dandy. The contradictory results from experiments on pineal gland feeding of animals and defective children, and the destruction of the gland in animals, prevent any conclusions being formed regarding the function and significance of this gland.

### 319. Treatment of Inoperable Cancer of the Breast.

R. MONOD (*Bull. et Mém. Soc. Nat. de Chir.*, February 4th, 1928, p. 92) records the case of a woman, aged 49, with cancer of the left breast and enlargement of the axillary glands. The tumour when first seen was the size of an egg; it was hard and adherent to surrounding structures. The glands were fixed and hard, and there was much pain in the arm from pressure on the brachial plexus. Removal by operation appeared impossible owing to the extent of the disease, and x-ray treatment was advised. Ten applications were given; three months later the tumour and glands showed marked diminution in size, and there was freedom from pain. Radical amputation was then considered possible, and this was performed satisfactorily. Examination of the tumour showed it to be a typical scirrhous with great increase of the fibrous tissue, probably produced by the x rays. The patient was well more than three years after the operation. The case illustrates the good results of the use of x rays combined with surgery.

## Therapeutics.

### 320. Calcium Chloride in Hepatic Ascites.

DESPITE unfavourable opinions as to the value of calcium chloride in the treatment of ascites due to hepatic cirrhosis, L. BLUM and P. CARLIER (*Presse Méd.*, February 25th, 1928, p. 241) strongly advocate its use in these conditions, and report three cases illustrating its beneficial action. Large doses of the salt were administered, in one case 360 grams being given in twelve consecutive days; during treatment common salt and substances containing it were rigorously excluded from the diet. The drug is said to be harmless even in these large doses, and in two of the cases the only ill effect was a slight diarrhoea lasting a day. The third patient, however, suffered from loss of appetite, acid regurgitations, constipation, and a sense of weakness, these symptoms disappearing on cessation of the medication. The absorption of the ascitic fluid and the resulting reduction of weight caused by calcium chloride are due to its diuretic action. Difficulties arising out of the unpleasant taste of this salt and its occasional gastric and intestinal reactions can be overcome by supervision of the patient. Large doses are very dangerous, however, in cases with only slight aqueous retention. Calcium exists only in small quantities in the secretions and tissues, and it is necessary, therefore, that all given in excess of the requirement should be eliminated or rendered inactive. Chlorine can be retained by the body in greater amounts, and large doses of calcium chloride cause an accumulation of chlorine without a proportional increase of the basic element, a chloro-acidosis resulting. In eliminating this excess of chlorine the kidneys combine the latter with the sodium (the principal base of the body), and, in the blood, the increase of calcium causes a decrease of the sodium; thus a chloro-acidosis with natropenia is produced—a condition analogous to that of nephritis with chlorine retention. Ascitic or oedematous liquids form an alkaline reservoir which provides the necessary base for the neutralization of the chlorine excess; in hepatic oedema where the quantity of liquid is small complications need not be feared. In the use of this drug in renal conditions where there exists a circulatory insufficiency, as in asystolia, or a secretory insufficiency, as in nephritis with oedema or chlorine retention. The authors believe that other calcium salts are useless in these conditions, since the chlorine is the essential factor; they emphasize the necessity of administering large doses of the drug over a long period, and of excluding salt from the diet meanwhile.

### 321. Local Treatment in Tabes Dorsalis.

A. LÖWENSTEIN (*Wien. klin. Woch.*, January 26th, 1928, p. 120) describes a method of injecting air into the spinal canal; this acts as a form of irritation therapy on a tabetic lesion in the central nervous system. The technique is as follows: 10 c.cm. of cerebro-spinal fluid are replaced by 5 c.cm. of air. The process of withdrawing 5 c.cm. of fluid and replacing it by air is then repeated four or five times, resulting in the substitution of 20 to 30 c.cm. of fluid by about 10 to 20 c.cm. of air. The patient is now slowly placed in the recumbent position and an hour later is given an intravenous dose of neosalvarsan. The process is repeated five to seven times at three-day intervals. The object of this treatment is to produce an aseptic localized irritation of the meninges of short duration. The author has found that only under such conditions were drugs able to pass from the blood to the cerebro-spinal fluid. The same principle of treatment is said to hold good in syphilitic affections of the eye, where subconjunctival injections of hypertonic salt solution or preparations of iodine cause an increased quantity of a blood-borne drug to reach the lesion. This form of treatment was found to be of most use in the early stages of tabes before neural atrophy sets in.

### 322. Treatment of Chronic Auricular Fibrillation.

E. P. MAYNARD, Jnn. (*Amer. Journ. Med. Sci.*, January, 1928, p. 55), reports that, by the use of quinidine sulphate, auricular fibrillation can be abolished in at least 50 per cent. of cases, and that, even with persistence of the irregular action, the patients are undoubtedly relieved and exercise tolerance is increased. In order to determine if this effect was sufficiently lasting to counterbalance the discomfort and danger of this drug, Maynard studied 53 cases of chronic auricular fibrillation treated with quinidine, and followed them for periods of one to five years. The drug was administered as follows. Two test doses of 0.2 gram each were given the first day in order to eliminate all possibility of hypersensitivity to the drug; if no symptoms appeared, the dose was increased to 0.4 gram every two hours for five doses. In the case of a few patients who failed to respond to this treatment the dose was cautiously increased to 0.6 or 0.7 gram every two hours.

Later, in one case, following the suggestion of Rieckor, 0.4 gram was administered every four hours night and day in order to produce an even action throughout the treatment. It was found that in 38 of the cases normal sinus rhythm returned, 25 remaining regular for one month or more, and 15 for at least six months. Various toxic rhythms were detected, including auricular flutter and paroxysmal ventricular tachycardia; one case of collapse and sudden death occurred following the administration of the quinine. Short duration of fibrillation was found to be a good prognostic sign, but there was a definite tendency for it to become permanent. Maynard concludes that in this form of treatment of chronic auricular fibrillation a careful selection of the cases must be practised, the two definite criteria for this purpose being, first, a relatively short duration of the fibrillation, and, secondly, a well-compensated heart without the signs of congestive heart failure.

### 323. Pilocarpine in Gall-bladder Disease.

J. M. IRGER and B. G. DRAGUN (*Wien. klin. Woch.*, January 26th, 1928, p. 127) confirm the observation that in non-obstructive cases pilocarpine, by stimulating the emptying of the gall-bladder, increases the excretion of bile. The action is similar to that of magnesia in that it is an irritant, but it also appears to paralyse the nistriped muscle of the gall-bladder and to inhibit the so-called gall-bladder reflex, thus permitting an unobstructed flow of bile. Given subcutaneously in small doses of 0.2 to 1 c.cm. of a 1 per cent. solution, it is said to be very beneficial in many forms of cholecystitis and cholelithiasis.

## Radiology.

### 324. Skia-graphy in Pulmonary Diseases.

LAQUERRIÈRE (*Journ. de Méd. et de Chir. Prat.*, January 10th, 1928, p. 34) insists on the importance of obtaining a series of skiagrams in every case of pulmonary disease examined by means of the fluorescent screen. While formerly it was impossible to obtain satisfactory films of the thoracic viscera on account of the respiratory movements, the modern rapid exposures (while the patient holds his breath), however, give sharply defined skiagrams. Although the fluorescent screen frequently furnishes important information, the image is indefinite and badly illuminated. Finer details are invisible to the observer and can be obtained only by instantaneous skiagraphy. Laquerrière condemns the too common dependence of specialists and general practitioners on repeated radioscopic examinations, which are misleading and do not provide a permanent record. A series of skiagrams taken at intervals is of great value in watching the progress of the disease.

### 325. Diathermy in Acute and Chronic Gonorrhoea.

L. L. MICHEL (*Med. Journ. and Record*, January 18th, 1928, p. 87) reports that in a series of two hundred cases of acute anterior gonococcal infections the results of diathermy treatment alone were not encouraging. The patients came for treatment from twelve hours to ten days after the infection, and were treated daily and thoroughly. After four weeks it was found that the diathermy had had no effect on the discharge or upon the destruction of the gonococcus in the secretions. In chronic anterior infections, however, diathermy proved very useful. Galvanism, applied by special electrode through the endoscope, gave excellent results in strictures, however impassable they had appeared. In involvement of the posterior urethra, prostate, and seminal vesicles diathermy had given its best results, surpassing any other form of treatment known; since using it Michel has rarely employed surgical intervention in posterior gonorrhoea, and has found that acute pus formation within the prostate was not a contraindication to diathermy. Gonorrhoea in the female yielded more quickly to this treatment than to any other form, chronic endocervicitis being controlled by one or two applications. The author decries limitation of treatment to diathermy, and thinks all available methods should be used in the treatment of gonorrhoea.

### 326. Tetra-iodo-phenolphthalein in Cholecystography.

To elucidate the results obtained by the use of tetra-iodo-phenolphthalein in the diagnosis of gall-bladder disease, J. H. KING and L. MARTIN (*Bull. Johns Hopkins Hosp.*, October, 1927, p. 219) studied a series of 407 cases of various clinical conditions in which this dye had been administered orally. The method employed was as follows. Twelve 5-grain capsules of the fresh chemical were given, four at 4 p.m., four at 4.30 p.m., and four at 5 p.m. Supper was given at 6 p.m., but no breakfast to the morning. Plates were taken at sixteen, nineteen, and twenty-two hours, and between the

last two a meal containing fats was given. Very few disagreeable symptoms resulted from taking the dye by the mouth, and in only one case were plates unobtainable owing to persistent vomiting. The patients were divided into two groups—namely, those who had undergone operations and those who had not; the latter were further subdivided into patients not suspected of having any gall-bladder disease and those with definite signs of such a condition. The former were grouped, as a result of the test, into those having a normally functioning gall-bladder, those with an abnormally functioning one, and those which did not show the faintest trace of the dye in the gall-bladder. From their observations the authors draw the following conclusions. This method will not give positive assurance that a normally functioning gall-bladder is organically sound, and may give misleading information. In normally functioning gall-bladders the resultant picture does not depend on the method of administering the dye, and there is a probability of error whether it be given intravenously or orally. In non-filling gall-bladders the test will not indicate definitely the presence of disease, though the possibility of error is less (20 per cent.). A so-called delayed filling of the gall-bladder cannot be taken as evidence of early gall-bladder or any other disease. The number of stones demonstrated by x rays after dye administration is decidedly greater than without it. The evidence afforded by this dye test is helpful but not absolute, and must be compared with the clinical symptoms of the cases under consideration.

327. OF the two methods of administering tetra-iodo-phenolphthalein Dr. L. VALACH (*Bratislavské Lekárske Listy*, February, 1928, p. 49) favours the intravenous route. It is said to be quite harmless if fresh preparations are used. The author distinguishes three types of gall-bladder: (1) the hypertonic or orthotonic bladder, (2) the atonic-ptotic bladder, and (3) the pathological bladder. The gall-bladder empties in two ways—first, actively through contraction of its muscular wall, and secondly, passively through relaxation of its sphincter. Active emptying has been observed only after intravenous administration of hypophysisin, but in cases of atony and cholecystoptosis the effect of hypophysisin was only slight and set in very late. Substances given by the mouth cause only passive evacuation of the gall-bladder, the most active in this respect being fats, yolk of egg, peptone, and magnesium sulphate. The atonic or hypotonic gall-bladder does not diminish in size after a fatty meal, but the intensity of the x-ray shadow diminishes greatly. The author considers that his experiments proved further the mechanical influence of the pregnant uterus upon the gall-bladder, favouring stagnation, which tends to gall-stone formation and infection. Whenever possible stereoscopic skiagrams should be taken.

## Obstetrics and Gynaecology.

### 328. The Uterine Muscle during Pregnancy and Labour.

H. KNAUS (*Wien. klin. Woch.*, January 12th, 1928, p. 45) has found in a series of observations on animal uteri (mainly rabbits) that spontaneous contractions occur in the non-pregnant organ which are comparatively infrequent and feeble before sexual maturity is reached, but become much more powerful and frequent subsequently, attaining a maximum at the rut period of the sexual cycle; if, however, the ovaries are removed this uterine activity ceases and atrophy supervenes. In order to study the activity of the uterine muscle at the different stages of gestation one horn of the uterus of a number of rabbits was rendered sterile by division of the tube under anaesthesia fourteen days before coitus was allowed. Thus only one horn in each animal became pregnant, while the consecutive changes in the musculature could be studied either *in situ* or by excising the sterile horns at successive stages of pregnancy—which in rabbits lasts thirty-two days—and plotting illustrative curves. Knaus reports that by the second day after coitus the spontaneous contractility and tone of the uterus is considerably reduced, and this condition persists till about the eighth day; this corresponds to the phase of gestation before the ovum is firmly embedded. On the tenth day irregular muscular contractions occur again, and the tone increases until by the fourteenth day the activity closely resembles that of the non-pregnant adult uterus. On the eighteenth day regular contractions, somewhat like feeble labour pains, begin; these contractions are arranged in groups separated by rest intervals of fairly constant duration, and gradually increase in power, reaching a maximum on the twenty-ninth day of gestation. Meanwhile the tone of the muscle has been increasing slowly, and from the thirtieth day onwards the increase in tone is much more rapid until the onset of labour. As a result of his observations Knaus came to the conclusion that there is no sudden change in the tone and activity of the uterus at the

onset of labour, but that, so far as these two functions of the uterine muscle are concerned, the latter part of pregnancy passes into the beginning of labour by orderly stages. Cases of precipitate labour are ascribed to a lack of perception of the dilatation of the birth canal. The increase of tone occurring in the human uterus during the last four weeks (the last tenth) of pregnancy corresponds to the last two days (also the last tenth) in the rabbit, and accounts for the diminution in size of the uterus observed to occur about this time.

### 329. The Production of Painless Labour.

E. VOGT (*Med. Klinik*, January 6th, 1928, p. 24) has used pernocton—a 10 per cent. solution of a barbituric acid derivative, also employed by surgeons and psychiatrists—for the production of "twilight sleep" in a series of over sixty cases without ill-effects to mother or infant. An average dose of 1 c.cm. per 12½ kilos of body weight is injected very slowly intravenously, when good pains are present and the os is dilated about 5 cm. in primiparae and 2 fingers in multiparae. If the correct dose has been administered the patient falls asleep immediately, but rouses sufficiently during the pains to use voluntary muscles if encouraged to do so, though the analgesic effect is almost complete and lasts for two or three hours. The preparation did not interfere in any way with the uterine contractions, it had no deleterious effect on the infant, it produced a sufficient anaesthesia for minor urgent manipulations such as the treatment of prolapsed cord, and was besides a useful preliminary, especially in nervous patients, for full anaesthesia when this was subsequently found to be necessary. Vogt adds that the vomiting which sometimes occurs may be prevented by a preliminary injection of atropine half an hour before the pernocton is administered.

### 330. Vulvo-vaginal Thrush.

ACCORDING TO M. R. LE BRAYÈ (*Gynéc. et Obstét.*, January, 1928, p. 40) vulvo-vaginal thrush is much more common than is usually supposed, and its alleged especial frequency in association with pregnancy and diabetes is due to the greater severity of the lesions in these two conditions. It occurs at all ages, but is more common in adult life, being about equally frequent before and after the menopause. In leucitis and candidiasis the infection is similar to that found in the following of which it is a notifiable, (1) which are de- but usually non-ulcerated mucosa. (2) Intertriginous or eozematous patches, most common at the vulva, especially over the internal surfaces of the labia majora or the external surfaces of the labia minora. (3) Vesiculo-pustular lesions, rarely larger than a pinhead, and most common on the skin near the vulva. Diagnosis can be made with certainty by microscopical examination of smears or cultures, and with the effect of specific testing of the (usually vaginal), reddened, sensitive, example, of a 1 or 2 per cent. sodium bicarbonate solution, made at least twice daily—are quickly effectual. Such treatment must be prolonged for some time after the pruritus has disappeared.

## Pathology.

### 331. Filterable Forms of the Scarletinal Virus.

U. FRIEDEMANN and H. DEICHER (*Zeit. f. Hyg. u. Infektionskrankh.*, January 30th, 1928, p. 354) have endeavoured to prove the existence of a filterable form of the scarlatinal virus, but without success. Throat washings from a patient with a severe attack of scarlet fever were taken on the second day of the disease, filtered through Berkefeld W candles, and the filtrate rubbed on to the throat of two persons with a strongly positive Dick reaction; both persons remained well. It was thought that perhaps the filterable virus acted only in the presence of streptococci, so in the next experiment the filtrate was rubbed on to the throat of four patients who showed numerous in throat smears. All these patients had a positive Dick reaction, but none of them contracted scarlet fever; one of them, however, developed scarlet fever four weeks later through infection at home. The authors conclude from these experiments and from other evidence that the existence of a filterable virus acting alone or in symbiosis with streptococci in the production of scarletina is improbable. A different question is whether filterable forms of streptococci exist. Ramsdine observed in certain batches of streptococcal toxin a flocculent

precipitate; on culture this proved sterile, but when injected into mice it infected them, and streptococci were later demonstrated in their organs. The present authors have endeavoured to repeat Ramsdine's observations. One batch out of six of toxin in which flocculation had appeared was found by them to be infective for mice; haemolytic streptococci were recovered in small numbers from the spleen and kidney. They have also examined the urine of patients with scarlatinal nephritis; one mouse out of seventy-four injected with such urine died, and haemolytic streptococci were isolated in large numbers from the blood, spleen, and kidneys. These successes are so uncommon that the author regards them as practically devoid of significance.

### 332. Reticulo-endothelial Blockage and Flocculation.

V. COSTABILE (*Il Morgagni*, January 22nd, 1928, p. 121) has studied the effect of blocking the reticulo-endothelial system on certain diagnostic reactions which depend on disturbance of the colloidal equilibrium of the serum. Such are: (1) Costa's reaction—positive in intoxications, infections, pregnancy, and malignant disease; (2) Brossa's reaction—due to a relative increase of the less hydrophilic colloids (fibrinogen, globulin) in the serum, and positive in malignant disease; (3) Botelho's reaction—depending on the easier flocculation of the less hydrophilic colloids in an acid medium by means of a solution of iodine in potassium iodide, and likewise positive in malignant disease; (4) Matcy's reaction—caused by the action of trivalent aluminium on globulin, and positive in tuberculous and all diseases in which there is active destruction of globulin. In addition to these reactions he studied the sedimentation rate of the red blood corpuscles, using Liuzenmoler's method on young male dogs. The blocking of the reticulo-endothelial system was effected by intravenous injection of a 1 per cent. solution of trypan-blue in saline, 3 c.cm. being given per kilo of dog. The reactions were practised on the two days preceding the blockage, and on each day following it, up to the fourth. It was found that after blockage all the reactions were rendered more positive than before; the time at which flocculation appeared was earlier, and the degree of flocculation was increased. With the sedimentation test the time taken for the blood cells to settle was considerably decreased. That the alteration in the reactions was due to a blocking of the reticulo-endothelial system, and not to the trypan-blue itself, was shown by control tests in which the dye was added to the serum *in vitro*. The author concludes that as a result of the blockage of the reticulo-endothelial system there is an increase of flocculating substances—albumins and globulins—which renders the reactions more intense. It is clear, therefore, that these reactions cannot have any specific value in diagnosis; they merely indicate a disturbance in the colloidal equilibrium of the body fluids.

### 333. Ambard's Constant and the Renal Functions.

A. OROFINO (*Rassegna internaz. di clin. e ter.*, December, 1927, p. 818), as the result of his investigations, comes to the following conclusions. (1) As regards the two functions of the kidney, excretion of water and the excretion of substances in solution, the chief of which is urea, Ambard's formula for denoting the area index in terms of the body weight can determine the latter but not the former. (2) Azotemia may be a sign of anemia, but is no means of showing slight renal changes. (3) The concentration of urea in the urine, as determined by use of the ureteral catheter, may serve for testing the comparative value of the two kidneys, but it is no indication of their functional value, since the excretion of urea depends on the albuminoid content of the diet. (4) Ambard's formula shows not only the state of the kidneys, but also their functional value. (5) In tuberculous lesions, a normal Ambard's constant is an undoubted sign of a healthy kidney, while a high figure points to bilateral renal lesions. (6) In urinary surgery it is of very great value, since it indicates whether an operation should be performed or not. If the figure exceeds certain limits it is dangerous to perform a nephrectomy or prostatectomy, whereas a good constant justifies any operation.

### 334. The Histamine Test for Gastric Secretion.

R. BRANCATI (*Il Policlinico*, Sez. Chir., January 15th, 1928, p. 18) reports a series of observations on sixty patients divided into three groups—those without gastro-duodenal lesions, those with gastric or duodenal ulcer, and those suffering from new growths. He injected 1 mg. of histamine subcutaneously and fifteen minutes later extracted and examined the gastric juice; he repeated this process six or seven times. Comparison with fractional test meals showed that this histamine test gave a constantly higher acidity curve. By the histamine method a pure juice is obtained which can be estimated without filtration, and is suitable for cytological or bacteriological investigations.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 335. Methyl Salicylate Poisoning.

THOUGH cases of methyl salicylate poisoning appear to be very rare, only thirteen cases with six deaths having been recorded, F. V. WOODBURY and A. G. NICHOLLS (*Canadian Med. Assoc. Journ.*, February, 1928, p. 167) point out that oil of wintergreen is a drug in rather common use and may be extremely dangerous. Accidents from its therapeutic administration seem to be unknown, due doubtless to its being prescribed for external use only, but it has been taken accidentally, for suicidal purposes, and as an abortifacient. The authors describe two fatal cases of poisoning with this drug, and review a case reported by Pincus and Handley last year. One ounce is usually regarded as a fatal dose, though recovery has followed the ingestion of this amount; on the other hand, less than 15 c.cm. has caused more than one fatality in infants. Where recovery has ensued the following symptoms and physical signs have been noted: vomiting, purgus, vertigo, general weakness, excessive appetite and thirst, rapid pulse, slow and laboured respiration, drowsiness, and air hunger; the appearance of acetone and diacetic acid in the urine; fever; contracted pupils and amblyopia; with tremors, hemiparesis, and mania. In fatal cases, convulsions, tonic spasms, and opisthotonos may develop, followed by cyanosis and collapse. The various authors emphasize epileptiform convulsions as the clinical cardinal feature in these cases. The outstanding pathological appearances are acute degenerative parenchymatous nephritis, acute gastritis, intense congestion and oedema of the lungs, and multiple small haemorrhages in the pericardium, pleurae, and beneath the dura. The convulsions and parietic manifestations are possibly due to vascular disturbances in the cerebral cortex.

### 336. Spirochaetosis Arthritica.

R. FRUEHWALD (*Urol. und Cutan. Rev.*, January, 1928, p. 7), who reports two personal cases, states that Reiter in 1916 described a peculiar form of arthritis associated with conjunctivitis and urethritis and a constant absence of gonococci. Hitherto only twelve cases, including the author's, have been recorded. The disease always begins with urethritis, which is followed by conjunctivitis and then arthritis. The inflammation of the urethra is usually severe, both the anterior and posterior urethra being affected, and in some cases pronounced cystitis develops. Involvement of the testes or vesiculae seminales has not been observed. The ocular condition commences with inflammation of the conjunctivae, which are greatly reddened, swollen, and discharge abundant pus. There may also be keratitis, corneal ulceration, and iritis. The arthritis always attacks several joints, especially those of the lower extremities. The first cases recorded by Reiter were very severe and were not affected by treatment, but their final issue was not recorded; subsequent cases have been much milder. Treatment is entirely symptomatic. Reiter isolated a spirochaete from the blood which he called *Spirochaeta forans*, but his findings have not been corroborated.

### 337. Epidemic Encephalitis.

R. CRUCHET (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, November 25th and December 10th, 1927, pp. 848 and 895) records in full the histories of 64 cases observed by him in 1917, when he gave the first description of the disease and adopted the following classification, which still holds good: (1) a mental form in which the cerebral torpor, amnesia, lack of orientation, changes in the pupils, tremor, dysarthria, paraphasia, and changes in the cerebro-spinal fluid at first suggested general paralysis; (2) a convulsive form in which there was a succession of fits which constituted a transient status epilepticus; (3) a choreic form with all the features of infective chorea in the adult; (4) a meningeal form in which the meningeal symptoms such as rigidity, Kernig's sign, pain in the back, somnolence, and vasomotor phenomena which were always associated with profound and persistent cerebral changes were not explained by any hitherto known factor; (5) a hemiplegic, or, rather, a hemiparetic form, which, owing to its rapid subsidence and arrest at a certain stage of its development, was quite different from the ordinary hemiplegia in the adult; (6) a pseudo-cerebellar form with ptosis, conjugate deviation of the eyes, titubation, and a simple cerebellar form closely resembling cerebellar tumour; (7) a bulbo-pontine form with various nuclear lesions affecting the

nerves in this region, such as the fifth and seventh cranial nerves, vagus, and spinal accessory; (8) an acute ataxic form, resembling in some respects toxic-infective polyneuritis; and (9) an anterior poliomyelitic form, resembling infantile paralysis.

### 338. Essential Thrombopenia with Haematomyelia.

K. EVANG (*Norsk Mag. f. Laegevid.*, February, 1928, p. 163) records a case in a man, aged 30, who had shown slight symptoms of the haemorrhagic diathesis from the age of 12 years, and suddenly developed, apart from any accident, symptoms of a complete transverse lesion of the spinal cord at about the level of the second dorsal nerve. During the course of seven months the disease passed through the stages of flaccid paraplegia, spastic paraplegia, and spastic paraplegia with extension contracture. Examination of the blood showed secondary anaemia, relative neutropenia and relative lymphocytosis, slight eosinophilia, blood platelets about 20,000 per c.mm., no retraction of the clot, considerably prolonged bleeding time, almost normal coagulation time, positive stasis test, and extravasation of blood on contusion and puncture. Evang regards the case as an example of chronic non-recurrent essential thrombopenia (Frank, Breslau) complicated by haematomyelia.

### 339. Tetanus Caused by Skin Dressings.

C. ARMSTRONG (*Public Health Reports*, December 16th, 1927, p. 3061) brings forward evidence to show that post-vaccination tetanus tends to follow severe primary vaccinations performed with large insertions and dressed with some type of shield or covering strapped to the site. Moreover, shields or dressings markedly predispose to the development of post-vaccination tetanus in monkeys or rabbits vaccinated with virus artificially contaminated with *B. tetani*. Armstrong defines a proper vaccination as one in which the insertion is not over an eighth of an inch in its greatest diameter, and is made by some method which does not destroy or remove the epidermis. Such insertions treated without shields or dressings strapped to the site have never been followed by tetanus. It is probable that such simple procedures on the part of vaccinators, coupled with a warning to the vaccinated individual concerning the dangers of home-applied shields and dressings, would eliminate tetanus as a sequel of vaccination.

## Surgery.

### 310. Echinococcal Cyst of the Liver.

A. BALDUZZI (*Il Policlinico*, Sez. Prat., January 30th, 1928, p. 129) discusses the differential diagnosis of echinococcal cyst of the liver. Contrary to the usual view he has found pain in the hypochondrium a prominent symptom. He fully discusses the symptomatology and comments on the disagreement in this respect. In his experience pain of a heavy character was the most dependable symptom; it was present in the right hypochondrium, and radiated in front to the epigastrium and behind to the shoulder and angle of the right scapula. Sometimes it was felt along the right side of the vertebral column behind and as far down as the groin in front. Such pain is not, however, pathognomonic. He reports three cases, in all of which pain was the predominant symptom, and in varying degree had persisted for years. The first patient, while under observation, for two days passed with the faeces fluid containing daughter cysts. No treatment was given, and the patient made a good recovery. In the second case the diagnosis was based entirely on the character and locality of the pain accompanied by fever. An exploratory puncture was negative, as also was the serological test. Pns and daughter cysts were evacuated by an operation, and the patient made a good recovery. The third case was diagnosed by pain and the position and hardness of a palpable tumour. At the operation the cyst was found to be calcified, as was expected.

### 331. Isolated Fractures of the Semilunar Bone.

A. ODASSO (*Chir. d. org. di movimento*, January, 1928, p. 1), who records two illustrative cases in men aged 53 and 39 respectively, states that isolated fracture of the semilunar bone is rare, only about thirty examples of the kind having been published. As a rule it is associated with fracture of the radius or other carpal bones. The etiology is the same as that of Colles's fracture, but semilunar fracture is peculiar

in that it only occurs during ulnar flexion of the hand, and is essentially due to one of two causes—namely, compression or tension exercised by the anterior radiocarpal ligament. The softening or so-called lacunae of the semilunar bone which have been described may in some cases predispose to fracture, but are usually the remote result of previous injuries or fractures which have escaped detection. Clinical diagnosis, though feasible in some cases, is often very difficult or impossible, and the most frequent error is to mistake it for a simple sprain of the wrist. To avoid this error systematic x-ray examination is advisable whenever the wrist is injured. The prognosis varies according to the case, and depends on the greater or less degree of severity of the initial lesion, the stage at which treatment was instituted, and the general condition of the patient. While in some cases the functional result is good, in others complications develop, such as pseudarthrosis, chronic arthritis, more or less complete ankylosis, considerable wasting of the muscles of the forearm, and weakness of the wrist. Treatment should consist of immobilization of the wrist-joint for eight to ten days, followed by hot baths, massage, and mechanotherapy. If these bloodless methods fail, and the fracture shows no tendency to unite, the semilunar bone should be removed as soon as possible.

### 342. Colloid Carcinoma of the Stomach.

ACCORDING TO J. W. STINSON (*Surg., Gynecol., and Obstet.*, February, 1928, p. 180) the first statistical studies of gastric carcinoma were published in the *British and Foreign Medical Review* in 1857 by Brioton, who, in a series of 135 cases, found that 9.4 per cent. were of the colloid type. In a series of 2,516 pathologically proved cases of carcinoma of the stomach examined at the Mayo Clinic from March 1st, 1913, to May 1st, 1925, colloid changes were found in 121, or 5.09 per cent.; 25 of these patients were women and 95 men, the average age of the women being 50.5 years, of the men 53.3 years, and the general age being 52.7 years. The oldest patient was aged 79 and the youngest 31. As regards the symptoms, there was nothing to distinguish colloid carcinoma from other types of gastric cancer. The only sure method of distinction consisted in exploratory operation and microscopical examination of the tissue. In structure colloid carcinoma resembles the ordinary adenocarcinoma of the stomach, except that a great deal of thin mucus is present. In typical cases the whole wall of the stomach is almost completely changed by the presence of colloid material, so that the cut surface is clear and gelatinous and of a soft consistency. Colloid changes may be noted in the earliest stages of the carcinomatous process, and are frequently found on microscopical examination when not visible to the naked eye, especially in cases of small ulceration, when the diagnosis lies between benign ulcer and carcinoma. In the present series 97 of the cases (80 per cent.) were operable and the growth was removed, 19 were inoperable, and 5 were suitable for palliative measures. The percentage of patients living three and five years after operation is about the same as in the non-colloid types of carcinoma, but the incidence of early recurrence is high in the colloid variety. The post-operative mortality rate is about the same as in the non-colloid types, the post-operative life expectancy being less in young patients.

## Therapeutics.

### 343. Treatment of Pernicious Anaemia with Liver.

J. C. SPENCE (*Newcastle Med. Journ.*, January, 1928, p. 71) recalls that Cohn, working on the liver treatment of pernicious anaemia, divided the liver into fractions, and, discarding those which proved inactive, has shown that the essential curative factor is probably a liver extract. This is a non-protein fraction representing about 1 per cent. of the liver, a few grams of which, taken daily by the mouth, act with apparent specificity. Spence reports the results in twenty cases of pernicious anaemia treated with liver and subsequently followed up. In nineteen of these the improvement was striking and rapid, some of the most severely ill patients being able to resume full activities in three months. The rapid disappearance of the glossitis was particularly striking. Treatment consisted in the daily addition of 1/2 to 1 lb. of lightly cooked ox-liver to the ordinary hospital diet. Later the amount was slightly reduced in some cases. Prolonged cooking of the liver is said to be very inadvisable, since this may destroy or decrease the potency of the active curative principle. Only one case showed no improvement, and it is suggested that this may not have been true pernicious anaemia. As a concentrated preparation could be more easily given than the liver itself, certain proprietary compressed liver tablets were tried in two cases but with little response. Later a concentration prepared by Cohn's method

was used, with beneficial results in two other cases. The number of reticulocytes rises during treatment, the climax being reached within seven days, and this may be considered as a rapid method of estimating the efficacy of treatment. Once the process of erythrocytic regeneration is established, the reticulocytes return to a steady level of 3 to 5 per cent. of the red cells. During treatment two patients had acute attacks of gout, and another had marked oedema of the legs due to venous thrombosis. These patients had eaten liver very freely, which suggests that the response to the diet is a quantitative one. Spence has found that when the red cells have reached 4½ to 5 millions per c.mm., no more liver should be taken than is necessary to maintain that level, 1/2 lb. four times a week probably proving sufficient. He believes that the discovery of an effective liver fraction indicates that pernicious anaemia is a disorder of an internal liver secretion, and that the work of Peabody disposes of the theory that the disease is the result of a primarily haemolytic process, the haemolysis being probably a secondary factor.

344. E. MEULENGRACHT (*Ugeskrift for Laeger*, February 9th, 1928, p. 123) has treated 21 cases of pernicious anaemia with a liver diet during the past year. At first he thought that raw liver must be more potent than cooked liver, and that doses, since found to be totally inadequate, would suffice. Hence the disappointing results obtained in his earliest cases. The first three patients, all of whom were very ill, obtained no benefit from 10 to 20 grams of raw liver a day (even this small dosage was not maintained consistently), and died. Of the remaining 18 patients 2 died, the necropsy in one of these cases showing malignant disease of a kidney and the lungs. In the other fatal case the cause of death was obscure, but it is possible that the fever and persistent diarrhoea may have been due to some intestinal infection which was aggravated by the constant presence of liver in the intestines. In all the remaining 16 cases the treatment proved most satisfactory. The blood picture showed marked improvement, and in those cases in which the tongue showed morbid changes they disappeared. In 2 cases there were severe spinal symptoms with paralysis and ataxia of the legs. The improvement effected in these patients was the more striking as, under other methods of treatment, such cases have hitherto been notorious for their progressive character. But when achylia was found, it appeared to be uninfluenced by the liver diet. Most striking of all was the improvement in the general condition, patients who had been debilitated finding themselves quite fit for work. The author was impressed by the fact that some of his patients preferred to take their liver in the raw state, either made up in a fluid form with oranges, or in lumps of 5 to 10 grams, wrapped up in paper, swallowed whole, and washed down with a little water. Others ate the necessary quantity (200 to 250 grams a day) in the raw state, minced and eaten with a spoon. Cat's liver was usually employed, for it was found that pig's liver had a more unpleasant taste. With regard to substitutes and extracts of liver, the author prefers to recommend whole liver until more is known of the active principles. He suggests that experience with this treatment may alter the existing views as to the pathogenesis of pernicious anaemia, and that, instead of being regarded as a condition caused by certain poisons introduced into the body, it may be proved to be a deficiency disease, in the same class as scurvy and beriberi.

### 345. Treatment of Acute Rheumatism.

G. ROSENTHAL (*Bull. Soc. de Thér.*, January 11th, 1928, p. 29) states that in acute articular rheumatism and allied affections such as chorea immediate and vigorous treatment is indicated in the form of intravenous injection of salicylates, as recommended by Lescné. However mild the case may be the intravenous route should be employed whenever there is a possibility of an endocardial localization. The method is also indicated in cases where there is gastric intolerance for salicylates. In the case of adolescents during the acute stage of acute rheumatism an intravenous injection of 1 gram of salicylate should be given morning and evening, combined with 6 grams by the mouth. As the symptoms subside a single intravenous injection should be given, combined with 3 grams by the mouth morning and evening, for a few days, when the intravenous injections may be stopped, while the treatment by mouth is continued.

### 346. The Iodine Treatment of Goitres.

L. DAUTREBANDE and A. LEMORT (*Bruxelles-Médical*, February 12th, 1928, p. 528) describe a modified iodine treatment of exophthalmic goitre and thyrotoxic adenomas. They have obtained good results by administering a solution containing 10 grams of iodine and 20 grams of potassium iodide dissolved in 100 c.cm. of distilled water. In Graves's disease at first 5 to 30 drops are given daily in two to four doses; then the dose is increased to 60, 100, or even 150 drops daily, the

dosage being regulated by frequent examinations of the basal metabolism. In adonomas a daily dose of 60 drops has never been exceeded. The authors believe that, in these conditions, the iodine acts by lowering the general metabolism, by reducing the activity of all the tissues and thus arresting the abnormal excitation of the thyroid gland, and by restoring to normal the disordered functioning of its internal secretion. They claim that, administered in this form, iodine is a valuable adjunct to the medical and surgical measures usually employed in these conditions.

## Laryngology and Otology.

### 347. Vestibular Neuritis in Acquired Syphilis.

D. MASSA (*Rev. oto-neuro-oftalm. y de cirugía neurolog.*, November, 1927, p. 312) describes two cases of lesion of the vestibular nerve some time after syphilitic infection. The first patient was a man, aged 20, who had been infected five years previously; he had attacks of vertigo, nausea, and vomiting, with nystagmus and nystagmus, which continued and rendered him unable to walk. Examination showed the middle ear to be normal, there was a spontaneous horizontal nystagmus, and Bárány's caloric tests indicated very reduced irritability. The fistula sign was absent and neither vestibule reacted to the galvanic test. The Wassermann reaction was positive. Hearing was good and the cochlea did not appear to be involved. The patient was given injections of mercuric cyanide and of pilocarpine hydrochloride on alternate days for a month, with an interval of six days in the middle on account of vomiting and diarrhoea. The second case was similar, but the vestibular symptoms occurred four months after infection; the cochlea was not involved, the labyrinth did not respond to caloric tests, and the rotatory tests gave diminished reactions. The patient was given mercuric cyanide and neosalvarsan on alternate days for three weeks, and became very much better, losing all the vertigo. Massa finds that vestibular neuritis in syphilitic cases comes on suddenly and that its symptoms are severe. The reactions of the labyrinth to stimuli are very much reduced, if not entirely abolished. The diagnosis is made on the sudden and severe nature of the labyrinthine symptoms and the history of acquired syphilis. He believes that with energetic treatment these cases can be cured.

### 348. Occurrence of Brain Tissue within the Nose.

D. GUTHRIE and N. DOTT (*Journ. Laryngol. and Otol.*, November, 1927, p. 733) remark that while the upward passage of a malignant growth from the nose to the brain is not particularly rare the downward extension from the brain to the nose does not appear to have been previously recorded. They describe two cases where brain tissue was present in the nasal cavity. The first patient was a man with symptoms of a rapidly growing frontal lobe glioma, which, in spite of a decompression operation, rapidly attacked the basal ganglia and caused death. The necropsy revealed a large glioma which had taken on malignant characteristics, had penetrated the dura mater at the olfactory sulcus, and had perforated the cribriform plate. A small tumour of neuroglial tissue was found in the nasal cavity, and on examination was found to consist of the same malignant tissue as the cranial growth. In addition, in one microscopical field, there were one or two thrombosed veins and a slight polymorphonuclear infiltration showing the earliest stages of a cerebral abscess. The second patient was a man who had had a blow on the head in 1911, since when he had suffered first from hemiplegia and later from paraplegia. Glioma of the frontal lobe of the brain had been diagnosed, but apparently incorrectly. In 1920 nasal obstruction had occurred, and in that year and in 1921 nasal polypi of the usual appearance were removed. In 1925 obstruction recurred and a further polypus was removed. This appeared to be more solid and fleshy than usual, and was therefore examined microscopically, and proved to contain glial cells and fibres. It was covered by a ciliated epithelium under which was a fibrous layer resembling the meninges. The recovery of this case was, from a rhinological point of view, complete. The authors consider that the first case was an example of a malignant growth forcing its way by pressure through the base of the skull into the nose, and the second to have been an encephalocele, the stalk of which had been nipped off by closure of the aperture of the base of the skull.

### 349. Tuberculosis of the Upper Respiratory Tract.

G. B. WOOD (*Arch. of Otolaryngol.*, December, 1927, p. 573) reviews recent work on tuberculosis of the upper respiratory passages, and discusses this infection of the larynx. He believes that invasion of this organ always occurs through small lesions of the mucous membrane and not through the

lymph system. The connexion between the tonsils and cervical glands and the interior of the larynx is of the slightest, and shows no signs of the transmission of tuberculosis. The four stages of laryngeal tuberculosis, according to Manassa following Aschoff, are as follows. (1) Infiltration; the mucosa is thickened, red, and studded with miliary tubercles, with a certain amount of round-celled infiltration, and possibly oedema. The oedema may be one of two types; in one there are large lymph-filled spaces in the connective tissue crossed by fine fibrils, while in the other there are multiple minute spaces between the bundles of connective tissue. (2) Ulceration; it has been shown that the necrosis in the larynx are not due to encasing tubercles, but to the extension of intact granulation tissue. (3) Perichondritis; when this is present there is usually very advanced destruction of the superficial tissues and some degenerative changes, at least in the cartilage. (4) Tumour formation; this may represent either a true tuberculoma or a pachydermia. The tuberculomata are rounded smooth swellings, only very rarely ulcerated, and are of two types—the fibro-tuberculoma, which is pedunculated, and contains a large proportion of fibrous tissue round the tubercles, and the granulo-tuberculoma, which is rarely pedunculated, and contains tubercles embedded in granulation tissue. Pachydermia only occurs where squamous epithelium is present. It is found in chronic simple laryngitis, but the tumour formation is much more marked in tuberculosis. Pachydermia may be the only evidence of tuberculosis, and must always be viewed with suspicion. In some cases of paralysis of the recurrent nerve in tuberculosis it is found that the nerve is not merely compressed by a mass of tuberculous glands, but is actually infiltrated and destroyed by a mass of tuberculous tissue.

### 350.

#### Mastoid Periostritis.

A. PIAZZA MISSORICI (*Arch. Ital. di Otol.*, December, 1927, p. 750), who records 110 cases of mastoid periostritis, has found that swelling occurs over the mastoid process, the temporal region, or both. The periostritis was unassociated with any underlying mastoiditis in over 50 per cent. of cases under the age of 5; in 45 per cent. between the ages of 6 and 10; in 44 per cent. between 11 and 18; and in 42 per cent. between 19 and 30. Above the age of 30 only 24 per cent. of swellings behind the ear were due to periostritis only, while the remaining 76 per cent. were caused by mastoiditis and periostritis. The site of the swelling gave no indication of the nature of the inflammation. Mastoiditis, as a rule, was accompanied by swelling over the mastoid alone, while, in simple periostritis, the swelling tended to spread to the temporal region or occurred in that area alone. Investigation of the nature of the microbic infection did not show any distinctive feature in the infection of each type of inflammation.

## Obstetrics and Gynaecology.

### 351. Radiological and Operative Treatment of Uterine Conditions.

C. J. GAUSS (*Med. Klinik*, February 3rd, 1928, p. 163) reviews the results of his own experience and various summaries in the literature of the radiological and operative treatment of haemorrhagic metropathies and fibromyomata of the uterus. He compares the two methods of treatment under the following headings: curative effect; mortality risk; complications; and social considerations, such as cost and loss of time. He mentions also the subjective preference of the patient for the more conservative method of treatment. He concludes that fibromyomata and haemorrhagic metropathies require active treatment if they do not react to medicinal or the simpler gynaecological measures. He considers irradiation of the ovaries to be the method of choice, and deduces from his own experience of over twenty years that the symptoms of the artificial menopause are more severe when produced in this way than by surgical treatment. Operation is indicated when the fibroid growths are pedunculated—either submucous or subserous—and torsion is likely or has already occurred. It is also advisable when it is desirable and possible to avoid amenorrhoea and sterility by a myomectomy, when there is evidence of degeneration or suppuration of a fibroid tumour which might lead to a spread of sepsis, and when the possibility of an ovarian tumour being present cannot be excluded. In all other cases of this type he considers operation unjustifiable. Gauss adds that the method of temporary sterilization to control haemorrhage and tumour growth in young individuals is still in its infancy. Because of the theoretical risk of damaging the ova, of which, however, he has no evidence, he limits the method of temporary or partial sterilization to those cases in which subsequent pregnancy is unlikely, or in which the condition

of the patient in other respects makes the risks associated with the form of irradiation the lesser of two evils. He approves diagnostic curettage as a preliminary to x-ray treatment.

### 352. Ectopic Gestation.

PÉRY, CHARRIER, and MAGENDIE (*Journ. de Méd. de Bordeaux*, January 10th, 1928, p. 1) report the case of a woman, aged 37, who had a miscarriage ten years ago, followed by slight menorrhagia. In November, 1926, she had a normal period, followed in January and February, 1927, by slightly coloured discharge. At the end of February she had severe colicky pains but without any vaginal discharge; the attack passed off in two or three days, but the abdomen continued to increase in size, and at the end of April the patient felt foetal movements. At the end of September she had labour pains but no delivery. In October she suffered from tachycardia, hypertension, and albuminuria. The foetal parts could be clearly made out. Lipiodol was injected into the uterus and its cavity was found to be enlarged but empty. On October 14th the abdomen was opened and a dead fully formed child was removed with the placenta. The authors believe that this was an abdominal and not a tubal gestation, for the walls of the foetal cyst were formed of a thin membrane suggesting the amnion, and there was nothing to implicate the tube. They lay stress on the necessity in these cases of finding suitable lines of cleavage in the removal of the mass. In addition to the above condition the woman had a small fibroid, which perhaps accounted for her history of menorrhagia, but it is doubted whether it had anything to do with the ectopic gestation.

### 353. Pernicious Anaemia in Pregnancy.

P. N. DESCHAMPS and A. FROYEZ (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 9th, 1928, p. 143) report a case of the above disease successfully treated by liver. A primipara, aged 27, and six months pregnant, was admitted into hospital in July suffering from extreme pernicious anaemia. The periods were regular up to five months; there was marked albuminuria and oedema, but the liver and spleen were not enlarged. The red corpuscles numbered only 1,800,000 per c.mm. She was given 250 grams of half-cooked liver for a period of twenty-six days, and three blood transfusions were performed. About a fortnight after the liver treatment was instituted a remarkable change for the better occurred. By August the red corpuscles had risen to 5 million and they remained between 4 and 5 million up to November, when the patient was in good health. In October she gave birth to a healthy full-term child and a mummified foetus. The surprising feature was the improvement in the blood while the foetus was still in the uterus; as a rule there is no improvement until delivery. The persistence of the periods for the first five months was also unusual. The authors do not think that the blood transfusion had nearly as much to do with the good result as the liver treatment.

## Pathology.

### 354. Bacteriolysis of the Tubercle Bacillus.

M. P. ISABOLINSKY and W. J. GITOWITSCH (*Zeit. f. Immunitäts. u. exper. Therapie*, January 16th, 1928, p. 285) find that certain oils are able to dissolve the tubercle bacilli, and that the lysates have a protective action against tuberculosis when injected into guinea-pigs. In their experiments tubercle bacilli were mixed in test tubes with cod-liver oil and with olive oil, and incubated at 38°C. for six months and at room temperature for four and a half months. Under these conditions the bacilli were largely dissolved; a few acid-fast bacilli could still be demonstrated, however, in films. Lysis was more active in the olive oil mixture, and was more complete when freshly isolated strains of bacilli were employed than when old laboratory cultures were used. Not all the bacilli were dead, for cultures of the deposit on egg medium sometimes gave a slight growth; this the authors think is due to the presence of lipid-resistant strains, which are able to multiply in the oil. A number of other oils were tested—animal oils, vegetable oils, and ethereal oils—but none was so active as olive oil. The authors consider it probable that the substances responsible for lysis are lecithin, olive oil, and oleic acid, and that their action is specific. Guinea-pigs were injected subcutaneously with some of the oil that had covered the tubercle bacilli and contained their disintegrated products; two injections were made at intervals of a week. The animals remained perfectly well. A month later they were injected subcutaneously with 5 mg. of a virulent culture of tubercle bacilli. The two animals used were killed after a month; one was completely free from tuberculosis, the other showed a local lesion only. The

experiment was repeated, but the virulent bacilli were injected intraperitoneally, as was also the olive oil. Two guinea-pigs died in three and a half months with slight tuberculous lesions; two others were perfectly well after that time, and when killed showed localized tuberculosis of the lungs; control guinea-pigs died of milary tuberculosis in twelve to nineteen days. The authors conclude that the action of the olive oil in the test tube mixtures was so to weaken the virulence of the bacilli that they served as a vaccine to protect animals against subsequent inoculation of virulent bacilli.

### 355. A Spontaneous Epidemic of Pneumonia in Monkeys.

B. WISNER (*C. R. Soc. de Biologie*, February 17th, 1928, p. 458) records the outbreak of a spontaneous epidemic of pneumonia in the monkeys at the Cantacuzène serological institute, Rumania. During the fortnight October 26th to November 10th, 1927, eight monkeys out of a stock of seventy-six contracted the disease and died. Necropsy showed in six cases a lobar pneumonia, in two cases a broncho-pneumonia; in all cases but one the lesions were bilateral. The pleura and peritoneum were each attacked once, and the pericardium twice; false membranes were found deposited on these serous membranes. In all cases the spleen was swollen. Microscopically a Gram-positive capsulated diplococcus was found in the lungs, spleen, and false membranes; it was recovered in culture from the heart's blood. Serologically the organism proved to be a Type II pneumococcus. A vaccine was made from some of the strains recovered; these were grown in a liquid medium for eighteen hours, centrifuged, and the deposit suspended in saline solution. Three doses were given of 0.1, 0.2, and 0.5 c.cm. subcutaneously on November 12th, 14th, and 17th respectively; no further cases of pneumonia occurred. The author draws attention to the points of similarity between this epidemic and those attacking human beings, particularly the morbid anatomy of the lesions and the presence of a Type II pneumococcus. He suggests that the vaccination was responsible for bringing the epidemic to an end.

### 356. Nature of Morbid Processes following Duodenal Obstruction.

S. SAITO, K. SAKAI, and S. SUZUKI (*Japan Journ. Med. Sci.*, June 27th, 1927, p. 43) have investigated acute intestinal obstruction experimentally to ascertain the cause of death in animals with duodenal obstruction, the factors influencing the occurrence of acute poisoning, and conditions which lengthen the life of animals; special attention was paid to the probable processes taking place in the intestine below the obstruction. The authors found that the incidence of rapid intoxication in duodenal obstruction is prevented and life is much prolonged when the bile duct, or the ureter, is transplanted into the duodenum just below the obstruction, thus allowing the bile, or the urine, to flow through the intestine, and that the same result followed irrigation of the intestine below the obstruction with normal saline. By anastomosing the duodenum with the colon, so that the duodenal contents flowed directly into the colon without passing through the small intestine, the animals showed signs of duodenal intoxication with extensive bleedings from the mucous membrane of the excluded intestine, but when the excluded intestine was daily irrigated with normal saline no signs of intoxication or bleedings occurred. It was further found that when the duodenal ingesta flowed through the whole course of the ileum without passing through the jejunum, or through about 30 to 50 cm. of the lowest ileum without passing through most of the small intestine, the animals survived without developing any signs of duodenal intoxication. These results point to the fact that the cause of rapid death in animals with duodenal obstruction lies in the altered condition of the small intestine mainly below the obstruction.

### 357. Gastro-entero-anastomosis and the Activity of the Gastric Glands.

M. P. BRESTKIN (*Arch. des sciences biologiques* [Russian], vol. xxvii, fasc. 4-5, p. 211), reports the results of his investigations on dogs after gastro-entero-anastomosis. The activity of the gastric glands is intimately connected with that of the pyloric part of the stomach, and gastro-entero-anastomosis interferes considerably with their normal function; it causes a continual flow of gastric juice. The reflex gastric secretion observed under normal conditions is not manifest in animals with gastro-entero-anastomosis, and in many cases there is even a diminution of the secretion during meals. Chemical stimulants cause an increase of the secretion as under normal conditions. Fat does not inhibit the secretion as it normally does, but the soaps formed in the duodenum stimulate the gastric secretion as usual.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 353. Protein Sensitiveness.

D. L. BARLOW (*Med. Journ. of Australia*, January 28th, 1928, p. 112), recognizing the importance of sensitiveness to foreign proteins in the causation of various pathological conditions, emphasizes the diagnostic value of testing the skin for sensitiveness and the employment of specific treatment. In hay fever and asthma protein sensitization is the underlying mechanism in their production, and it is important that patients should be tested early in order that the protein concerned may be avoided, or that desensitization may be effected before the condition has become chronic or complicated. Scratch testing is said to be better than intradermal injection as a routine for pollen and epidermal proteins, though it may often be necessary to resort to the latter method in order to demonstrate sensitiveness to food and bacterial proteins. While specific desensitization treatment is indicated when it is impossible to avoid contact with the offending protein, it must not be regarded as the whole treatment of the affection. The general management of an asthmatic condition and the elimination of contributory causes, such as sinus disease or infected feet elsewhere, are most important in treatment. While many hay-fever patients obtain temporary relief by local treatment, desensitization by inoculation with the offending proteins should be performed also. In pollen asthma pre-seasonal treatment should be adopted with desensitization treatment as early as possible, and not postponed until other measures have failed. Epidermal asthma generally responds well to treatment, but further inoculation may be needed later. Barlow considers that vaccines prepared from sputum or nasopharyngeal swabs are frequently valuable in asthma which is not due to pollen, food, or epidermal proteins, but for this purpose only those organisms causing reactions should be incorporated in the vaccine after the patient has been tested with pure sterilized cultures intradermically.

### 359. Heart Affections in Elderly People.

A. G. THOMAS (*Journ. Med. Assoc. South Africa*, February 11th, 1928, p. 56) has analysed 46 cases of heart disease, excluding valvular lesions, in patients over 50 years of age. These patients, half of whom were men, showed myocardial damage due either to toxæmia or to arterio-sclerosis. The commonest symptoms in order of frequency were found to be dyspnoea on exertion or even at rest, pain or discomfort in the cardiac region, insomnia, sometimes due to dyspnoea, and slight swelling of the ankles. Little was generally discovered on physical examination; there were no murmurs and no enlargement of the heart; occasionally dropped beats were detected and a slight increase in the blood pressure. Several patients complained of epigastric pain and breathlessness, and it was found that an increased risk of sudden death was associated with this syndrome. The conditions giving rise to non-valvular heart disease in this group of patients were high blood pressure, senile degenerative changes, and toxæmias from acute infections such as influenza and pneumonia, but chronic interstitial nephritis was not prominently an etiological factor. Acute digestive disturbances were apt to produce changes of rhythm and sudden collapse in this type of case. The author regards general regimen and relief of symptoms as the most important lines of treatment; he recommends ample rest, a congenial environment, and moderation in diet with restriction of meat. The response to digitalis is said to be often disappointing, but a mixture of nux vomica, potassium iodide, and bromide was found to benefit the majority of patients.

### 360. Congenital Syphilis.

R. FISCHL (*Med. Welt*, February 18th, 1928, p. 243) believes that the great majority of cases of congenital syphilis are due to infection through the placental circulation, and not by contact with maternal lesions at the time of birth. He has observed 164 cases in the last ten years. Among these, 11 infants exhibited symptoms during the first week after birth; in 84 cases symptoms appeared in the second week. In the third week only 17 showed signs of congenital infection; while 63 developed symptoms between the third week and the sixth month. Thus the great majority of cases occurred during the second week of life, and 59 cases (35.98 per cent.) exhibited symptoms between the tenth and twelfth days. In Fischl's personal experience the percentage of

cases of congenital syphilis is now very small, approximately 0.25 per cent. He reports a remarkable decline in the number of cases during the last two years, coincidently with a more intensive treatment of parental syphilis. He has obtained no evidence that the intensive treatment of congenital syphilis induces visceral lesions instead of superficial manifestations. He finds that a negative Wassermann reaction occurs relatively frequently (nearly 22 per cent.) in infants presenting symptoms of florid syphilis, and concludes, therefore, that this test is of little value in doubtful cases; examination of the conjunctival and nasal secretions for the presence of spirochaetes is said to be a much more reliable method of diagnosis. Fischl maintains that the passage of spirochaetes from mother to child does not depend directly on the condition of the mother's lesions, for in some cases these were found to be definitely regressive or healed. He thinks that the possibility of direct paternal infection has not been disproved, and he believes in the existence of the "Colles's mother," with a negative Wassermann reaction.

### 361. Toxic Diphtheria.

W. STEINBRINCK (*Med. Welt*, March 3rd, 1928, p. 327) reports that in Breslau there has been during the last two years an increase in severity in cases of diphtheria, as also in Berlin and several other German towns. The cases were characterized less by increased frequency of laryngeal obstruction and its complications than by diffuse foul-smelling pharyngeal deposits, glandular enlargement, periglandular oedema, and severe toxæmia, which frequently led to vasomotor paralysis, cardiac dilatation, and death in the first or second week of the disease. An attempt to prevent the occurrence of toxic symptoms by early and large doses of antidiphtherial serum failed to reduce the mortality. It has recently been suggested in Berlin that the severity of the toxæmia is due to a mixed infection with streptococci, and combined injections of antidiphtherial and antistreptococcal serum have been used. Steinbrinck also found antistreptococcal serum of great value in his toxic cases.

## Surgery.

### 362. Surgical Treatment of Pulmonary Abscess and Gangrene.

G. PICOT (*Arch. méd.-chir. de l'appareil respiratoire*, 1927, Tome II, No. 4, p. 353) comments on the difficulty in pulmonary suppuration of determining the site or size of the abscess, its depth, multiplicity, and even its very existence; moreover, septic lesions may exist near the abscess and may so modify the symptoms as completely to mask it. Pulmonary abscesses may be classified as non-fetid, caused by specific organisms (streptococci and pneumococci); fetid, due to specific bacteria; and putrid or gangrenous, in which a multiplicity of organisms, particularly anaerobes and spirochaetes, are found. Non-fetid abscesses can heal spontaneously, do not cause a marked failing of the general health, and, being encapsulated, are circumscribed. Putrid abscesses are of graver prognosis, and, becoming subacute or chronic, usually end fatally in about two years. These abscesses exist as cavities in the parenchyma, are non-encapsulated, and the walls are broken, torn, and covered with gangrenous debris. Marked pulmonary sclerosis, especially round the bronchi, accompanies these lesions. Spontaneous cure is very rare, and medical treatment is often insufficient, since the cavity cannot be completely obliterated, thus causing danger of a recurrence. Surgical intervention aims at draining the abscess and producing its obliteration and cicatrization; it necessitates precise diagnosis of the lesions. Repeated radiographs should be made, and an exploratory puncture is an excellent aid to diagnosis. Picot does not favour bronchoscopy, which he considers dangerous and almost useless. Pneumotomy, by which the abscess can be drained to the exterior, should be performed only when the infected area is limited and the pus has already collected; it should be practised under local rather than general anaesthesia, since the latter favours septic complications of the opposite side. Other abscesses should be drained into the bronchi by one of the collapse procedures, such as artificial pneumothorax, phrenicotomy, or thoracic plastic operations. Phrenicotomy does not give conclusively good results, and one of the other operations is preferred by Picot.

**363. Splenectomy for Purpura Haemorrhagica.**

A. W. SPENCE (*Brit. Journ. Surg.*, January, 1928, p. 466) remarks that splenectomy was performed for purpura haemorrhagica on the assumption that the haemorrhages were the result of the reduction in the number of blood platelets caused by the destructive action of a diseased spleen. It is thought that the prolongation of the bleeding time is due to a defective quality of the platelets rather than to diminished numbers. The transfusion of citrated blood in these cases results in a fall in bleeding time to normal and a temporary rise in the platelet count. Purpura haemorrhagica may be divided into acute and chronic cases; splenectomy is beneficial in 80 per cent. of the chronic and 16 per cent. of the acute cases. When splenectomy is successful there is a decrease in the bleeding time to normal and an increase in the platelet count. Two cases are described which show the value of splenectomy as a therapeutic measure. In chronic cases its effects are said to be so beneficial as to warrant its performance when the diagnosis is made.

**364. Diverticula of the Duodenum.**

H. BLANC (*Bull. et Mém. Soc. Nat. des Chir. de Paris*, February 17th, 1928, p. 116) discusses the subject of diverticula of the duodenum. The false or secondary diverticula are usually the result of some inflammatory condition or due to an ulcer. True diverticula are congenital in origin, and the name should really be confined to this group. These diverticula are usually found in the second part of the duodenum, and there may be two or three present in the same case. The symptoms are not typical, and are usually similar to those of other gastro-intestinal lesions; there are generally indefinite dyspeptic troubles aggravated by food, but vomiting does not occur as a rule. In some cases, however, vomiting has been marked, suggesting pyloric stenosis, while jaundice and symptoms of chronic pancreatitis have also been noted. The diagnosis is always made by radiography. The treatment of choice is resection of the diverticulum and closure of its mouth in two layers. Invagination has also been practised. If these procedures cause narrowing of the duodenum it may be advisable to perform a gastro-jejunostomy also.

**365. Torsion of the Omentum.**

G. L. MCWHORTER (*Arch. of Surg.*, February, 1928, p. 569) finds that pure torsion of the omentum, unassociated with hernia, adhesions, or tumour, is rare, and records two cases. This condition may arise without any pre-existing abdominal symptoms. There appears to be in all cases evidence of a pre-existing pedicle which may be congenital in origin. Obesity of the omentum is usually present, and is a frequent predisposing factor in the condition. Hyperaemia may be the exciting factor in torsion, although trauma or unusual exertion may initiate it. Early operative resection of the strangulated omentum should be performed. Prophylactic treatment consists in resection of a pedunculated omentum and the freeing of adhesions when found at an operation.

## Therapeutics.

**366. Treatment of Osteo-articular Tuberculosis.**

C. CLAVELIN and A. SICARD (*Presse Méd.*, February 22nd, 1928, p. 227) have combined intravenous injections of calcium chloride with ultra-violet irradiation in a large number of severe cases of osteo-articular tuberculosis. They always use freshly prepared weak solutions (never more than 1.5 per cent.  $\text{CaCl}_2$ ) of the chemically pure salt in distilled water. The solution is repeatedly filtered, then sterilized in an autoclave. They give two series, each of ten injections, administered on alternate days. An interval of twenty days' rest is permitted before the second series of injections is commenced. In the first series five injections of a 1 per cent. solution are given in progressive doses of 50 to 250 c.cm., and then five injections of a 1.25 per cent. solution in similar dosage. After the twenty days' interval, five injections of a 1.25 per cent. solution in doses gradually increasing from 50 to 250 c.cm. are followed by five more injections of a 1.5 per cent. solution in similar dosage. In two months the patient receives a total quantity of 30.5 grams of the salt, of which 50 per cent. is absorbed (Delore). The flask of solution is first heated in a water-bath to 40° C.; its contents are then poured into a graduated funnel with a rubber tube, to which the needle is attached. If the vein is not entered a blister will be seen and the injection is stopped at once. When an intravenous injection is given, the patient feels a sensation of heat in the head, sometimes through the whole body; occasionally there is a "chalky fasto" in the mouth, or even slight nausea. When it is better to stop the injection lest vomiting should occur, though this seldom happens if the solution is injected very slowly. At least five minutes should be allowed for the

injection of 100 c.cm., and immediately afterwards the ultra-violet treatment is given. Irradiations are repeated every second day during the injections and the interval between the series. The patient receives in all thirty general irradiations. The first irradiation lasts for one minute with the lamp at a distance of one metre. Every subsequent irradiation is increased by one minute, and the patient is brought nearer the lamp. The final irradiation lasts for thirty minutes with the lamp at a distance of 0.5 metre. Usually the injections are well borne; the pulse is not changed nor does the temperature rise. The injections should not be given immediately after food, and the tolerance of the patient should be observed closely. Only one case of intolerance was seen; the patient fainted, but was restored quickly by an injection of adrenalin. In some advanced cases with pulmonary tuberculosis, rigors and profuse sweating followed the injections; in such cases it is advised that the dosage should be increased more gradually. The results have been generally satisfactory. Of 28 patients, 4 lost weight slightly, but 17 others gained from 5 to 20 lb. Many fistulae grew smaller and then healed. The authors consider that the combined treatment enables the patient to fight better against the disease.

**367. Vaccine Treatment in Soft Chancre.**

M. GARRIGA (*La Med. Ibera*, March 10th, 1928, p. 261) records 65 cases of soft chancre treated by Nicollo's vaccine, his conclusions being as follows. (1) The vaccine can be given intravenously and intracutaneously. The intravenous method is undoubtedly the most efficacious, although it gives rise to certain reactions, especially a high and continued fever. The intracutaneous method is less efficacious and slower in its action, but has the advantage of not giving rise to any general reaction. (2) The therapeutic effect of the vaccine, whether given intravenously or intracutaneously, is very slight in the case of ordinary chancroid. It is when the soft chancre and the secondary ulcers become abnormal by their extent and depth that vaccine therapy is valuable. (3) Vaccine treatment by the intracutaneous route is indicated, therefore, as a prophylactic against complications in the case of ordinary chancroid, and as a curative treatment in abnormal chancroid and secondary ulcers. In such cases the vaccine should be given intravenously if possible. (4) Intravenous vaccine therapy is contraindicated in old and weakly patients, in subjects of cardiac, renal, and hepatic disease, and in latent or active tuberculosis. In such cases, however, intracutaneous injection involves no risk.

**368. Synthalin in Diabetes.**

M. LABBÉ (*La Vie Médicale*, February 10th, 1928, p. 161) discusses the value of synthalin in diabetes, and refers to the copious literature. He agrees that the dose should be 20 mg. twice a day with meals, with a possible increase to 25 or 30 mg., but as its action is cumulative, the administration should be discontinued for one day in every three, if the drug is well tolerated and no gastric symptoms such as anorexia, epigastric oppression, diarrhoea, or vomiting occur. Those disturbances and the possible partial or complete anuria are seldom sufficiently serious to necessitate stopping the treatment; they are said to be due to a direct action on the sympathetic nervous system, and may occur when the drug is injected hypodermically. Calcium carbonate, belladonna, bromides, and bile extracts have been given as antidotes. Glycosuria is not diminished immediately, but the action of the drug is very definite after three days. The reduction is proportional to the dose administered, 1 mg. usually reduces glycosuria to the extent of 1.2 grams. While insulin can be administered safely for a long time in large doses, synthalin is dangerous in larger doses than 50 mg. daily. It cannot replace insulin in the treatment of acidosis, while its action in hyperglycaemia is slower. In young patients synthalin does not arrest emaciation, and toxic symptoms may occur. It cannot replace insulin in those cases in which the latter has failed. Labbé's personal experiences of synthalin accord with that of other authors—that its toxicity is a serious obstacle to its general use. He adds that it will never replace insulin in severe diabetes, especially when emaciation and acidosis are present; it is ineffective in diabetic coma, and its utility is restricted to mild cases in which insulin is unnecessary.

**369. Sodium Salicylate in Chronic Epidemic Encephalitis.**

S. H. EPSTEIN, R. K. FARNHAM, and S. COBB (*Boston Med. and Surg. Journ.*, February 16th, 1928, p. 1552) state that the favourable influence of salicylates on certain forms of encephalitis was not recognized until 1923, when Carnot and Blamontier treated two patients with acute epidemic encephalitis by intravenous injections of sodium salicylate. Since then numerous cases have been reported of acute epidemic encephalitis treated by intravenous injection of

sodium salicylate with more or less success. Only a few cases, however, of post-encephalitic Parkinsonism have been treated in this way, but the results were less successful. The present authors record two cases of Parkinsonism in patients aged from 15 to 44, who were given intravenous injections of 2 grams of sodium salicylate in 20 per cent. solution at weekly intervals. Although subjective improvement was noted in nearly every instance, little or no real benefit resulted. The improvement was only transitory, and the progress of the disease was not arrested. Local venous thrombosis occurred in every case. To prevent this the authors suggest that oral administration should be tried in future, and that it might be more effective than intravenous doses owing to the continuity of administration.

## 370.

## Treatment of Asthma.

ACCORDING TO C. SUTHERLAND (*Med. Journ. of Australia*, January 7th, 1928, p. 2) rather more than half the cases of asthma are due to specific hypersensitivity; in many of the remainder some focal sepsis can often be found. The exciting substance in the first group is probably allied to histamine, and treatment should be directed to preventing its formation or combating the spasm. By skin tests the exciting cause may be detected, when the patient may be desensitized by injections of the substance to which he is sensitive. For those who do not react to these tests such vaccines as the anti-influenza may be tried, or intravenous peptone, tuberculin, autohaemotherapy, shock protein therapy, x rays, and diathermy. Adrenaline, in small doses given early and repeated every ten minutes, is still the most useful, and pituitrin is efficacious; ephedrine given by the mouth is slower in action, but its effect is more lasting. Morphine and atropine, or light chloroform anaesthesia, may be useful in severe cases. Between the attacks sodium iodide is better than the potassium salt, and in children arsenic is often beneficial. Authorities differ as to the advisability of special diet unless there is definite dyspepsia; in children it is best to cut down the carbohydrates. Attention to the general hygiene is a necessary part of any course of treatment. Sutherland adds that the results of removing nasal polypi in these cases are often disappointing.

## Ophthalmology.

## 371.

## Lymphoma of the Lacrymal Sac.

H. WEVE (*Nederl. Tijdschr. v. Geneesk.*, February 11th, 1928, p. 696), who records an illustrative case, states that tumours of the lacrymal sac are very rare, so that many ophthalmologists of extensive experience may not have seen a single case. Schirmer, in the first edition of Graefe-Saemisch's *System*, does not mention the subject. In a later edition Stock, in addition to carcinoma and sarcoma of the lacrymal sac, alludes to a case reported in 1881 by Creutz, who found a lymphoma of the lacrymal sac in a patient suffering from leukaemia. Weve's case occurred in a woman, aged 59, who had suffered from lacrymation for a year, but had only had a swelling of the lacrymal sac for six months. The blood picture was normal, but the patient had had an enlarged cervical gland for six months. Toti's operation was performed and a yellowish-grey nodular tumour was extirpated. On microscopical examination it was difficult to determine whether the growth was a round-celled sarcoma or a lymphoma. The last diagnosis, however, appeared the more probable, since the wall of the sac and the lacrymal duct had a lymphatic structure, and lymphoid growths show a predilection for such situations. Comparison of the sections with lymphomata of the lacrymal gland and conjunctiva, and colloidal preparations of the tumour of the lacrymal sac, confirmed the view that the growth was a lymphoma. The only similar case was one recorded in 1927 by Pascheff at the forty-sixth congress of the German Ophthalmological Society, in a man, aged 70, who had a bilateral lymphoma of the lacrymal sac. The blood picture was normal. There was recurrence one year after removal of the growths, but this was successfully treated by x rays.

## 372.

## After-results of Cataract Extractions.

R. C. DAVENPORT (*Brit. Journ. of Ophthalmol.*, February, 1928, p. 85) analyses all the cataract extractions performed at Moorfields Eye Hospital during the years 1919-25, and compares them with a similar analysis made at this hospital by Devereux Marshall for the years 1889-93. By far the most popular technique employed in the recent series is extraction with peripheral iridectomy. The losses from acute infection appear to be considerably lower in recent years. With regard to visual results, those with simple extractions and those with peripheral iridectomies are better than those with complete iridectomy, but against this must be remembered the

fact that at the present time complete iridectomy is often performed in complicated cases. Compared with the earlier series prolapse of the iris is more common in all forms of technique. This may be explained by the more frequent extraction of immature cataracts. The visual results after iris prolapse are, however, better in the recent series. Vitreous loss is about the same in both series, and was considerably more common after complete iridectomy. Only four cases of sympathetic ophthalmia occurred in the recent series, as compared with eight in the earlier series. There were a great many more needlings necessary in the recent series, probably again owing to the greater number of immature cataracts operated upon nowadays. The total number of cases in the 1889-93 series was 1,519, and in the 1919-25 series 2,368.

## 373.

## Obstruction of Branch of Retinal Vessels.

F. H. RODIN (*Amer. Journ. Ophthalmol.*, October, 1927, p. 753) describes a case of obstruction of a branch of the superior temporal artery of the left eye which supplied the macula. The patient had complained of headache for some months. On examination a partial central scotoma and a small relative inferior paracentral scotoma were found. He remarks that the interest of the case lies in the fact that from the lower temporal border of the disc a cilio-retinal vessel extended towards the macula, and in consequence a portion of macular vision was retained. In cases of embolism of the central artery of the retina it is stated that the presence of a cilio-retinal artery, which occurs in 16 per cent., sometimes saves central vision.

## 374.

## Diphtheria Antitoxin in Sympathetic Ophthalmia.

E. B. HECKEL (*Arch. of Ophthalmol.*, January, 1928, p. 54) describes this method of treatment in four cases of this condition. The result was favourable in all four cases. In the first case five doses of diphtheria antitoxin, each of 3,000 units, were given. In the second case, after an initial dose of 1,500 units, four doses of 3,000 units were injected at intervals of a week. Only slight improvement occurred, so the dose was increased to 20,000 units, which was repeated daily for four days, when very considerable improvement ensued. The third case was a child, aged 6 years; 5,000 units were given daily for ten days with very good result. The fourth patient was given 20,000 units daily for seven days, with the result that the sympathizing eye regained full vision, after being reduced to 2/200. Heckel emphasizes the need for large doses of the antitoxin.

## Obstetrics and Gynaecology.

## 375.

## Spinal Anaesthesia in Labour.

P. BALARD and R. MAHON (*Presse Méd.*, March 7th, 1928, p. 291), discussing the advantages gained by spinal anaesthesia in labours complicated by spasmodic rigidity of the cervix, state that this rigidity is really an arrest of dilatation due to a state of uterine contraction. Demelin showed that the intracervical mucosa is lined with fine transverse muscular fibres, and the present authors agree with Keiffer that the cervix is a veritable sphincter. Cases are rare in which the muscular bed is so developed that its contraction alone can be dystocic, and most frequently the arrested dilatation is due to a generalized uterine contraction, of which the cervical rigidity is only a local manifestation. In the majority of cases of arrested dilatation due to cervical contraction time, rest, and opiates produce very good results, but often the maternal and foetal interests demand a more rapid termination of labour. The irritation caused by mechanical dilators is liable to increase contraction without accelerating dilatation. Two methods come up for consideration—namely, manual dilatation and incision of the cervix. The former, very efficient in the simple cases of multiparae, is painful and liable to cause cervical tears in primiparae; in these cases the authors strongly advocate spinal anaesthesia. By producing a physiological section of the posterior roots of the cord, this method suppresses the pathological hypertony, and even the normal tonic, of the cervix, and permits an easy and sometimes spontaneous dilatation. The contraction of the body remains unchanged as the autonomous uterine nervous system, freed from the moderating control of the medullary centres, produces a hypertony. Ballard and Mahon inject 5 to 7 cc. of syncaïne, and use manual dilatation, if necessary, when the flaccidity of the vulva and anus indicates an atony of the soft parts. No risk to mother or child is involved by this method, and the puerperium remains unaffected. Spinal anaesthesia is useless in pathological or primarily infective rigidity, but in normal contraction or in cases of secondary infection it is a most efficient method of producing speedy dilatation.

Y. BOURDES (ibid., March 10th, 1928, p. 316) draws attention to the dangers attending spinal anaesthesia in total or subtotal abdominal hysterectomy, and reports an illustrative case. The great atony of the anal sphincter occurring during this anaesthesia constitutes a serious risk, since it permits soiling of the operative field by the faeces. In these cases Bourdes strongly advises that an enema be given on the morning of the operation, and that, after the pudendal toilet, the vaginal entrance should be closed by well-packed sterile gauze.

### 378. Separation of the Symphysis.

W. BREHM and H. V. WEIRAU (Amer. Journ. Obstet. and Gynecol., February, 1928, p. 187), as the result of a systematic x-ray study of pelves before and after delivery, were surprised at the amount of separation of the symphysis pubis which occurs in apparently normal labours. In their last series of 54 cases 25 were normal without any separation, slight separation (0.5 to 0.9 cm.) was noted in 15, moderate separation (0.9 to 2 cm.) in 13, and severe separation (more than 2 cm.) in one case. Slight separation gave rise to no symptoms, but moderate separation caused pain over the pubes on turning, and fear of moving because of the unpleasant sensation occasioned there. The authors state that copritation may be felt; there is usually retention or incontinence of urine, with possibly prolapse of the urethra and bladder; there may be sudden pain due to the soft parts getting between the separated bones, and cystitis is common. Similar symptoms, but more pronounced, occur in severe separation. It is recommended that slow labours should be treated with scopolamine and morphine, and that the entire pelvis should be strapped and handaged after delivery. The bladder should not be allowed to become distended, and after catheterization one ounce of 5 per cent. argyrol solution should be introduced. The patient should be kept in bed for from three to four weeks, and a bandage be worn for three months after getting up. If symptoms persist surgical apposition may be necessary. An x-ray examination should be made if there is any suspicion of disproportion between the foetus and the pelvis.

### 377. Ulcus Vulvae Acutum.

W. L. L. CAROL and A. CHARLOTTE RUY (Nederl. Tijdschr. v. Geneesk., January 28th, 1928, p. 396), who record three illustrative cases, state that Lipschütz, in 1912, described under the name of "ulcus vulvae acutum" a specific form of gonital ulceration associated with the presence of an organism which he called *B. crassus*, and which was first obtained in pure culture by Scherber in 1913. Between 1913 and 1923 Lipschütz and Scherber recorded about twenty cases, and altogether about sixty cases have been described in various countries, including Austria, Germany, Poland, Denmark, England, Italy, and the United States. The first case in France was recorded by Roederer and Stoimovici of Strasbourg in 1927. The localization of the ulcers is the inner aspect of the labia minora, the free margin of the labia majora and minora, the introitus vaginæ, perineum, anterior and posterior commissure, and preputium clitoridis. Three forms have been described—namely, a gangrenous form of sudden onset, causing more or less destruction of the labial muor; a venereal form consisting of multiple ulcers resembling soft chancres; and a milinary form characterized by the presence of ulcers the size of a pin's head. Ulcers resembling ulcus vulvae acutum in which *B. crassus* was present have been found in men at the root of the penis, perineum, and round the anus. Ulcers have also been found on the vulva similar in appearance to those described, but in which *B. crassus* was not present. *B. crassus* has been found, apart from ulcus vulvae acutum, in vulvitis, cervicitis, salpingitis, and non-gonorrhoeal urethritis in women, especially in prostitutes. In some cases ulcus vulvae acutum has been associated with aphthous stomatitis, as in one of the authors' cases, in a woman, aged 24, in which *B. crassus* was found both in the buccal and vulvar lesions. The authors emphasize the forensic importance of ulcus vulvae acutum, since the patients may wrongly be suspected of venereal disease.

## Pathology.

### 378. Absorption of Oily Subcutaneous Injections.

L. BINET and H. BINET (Rev. de Méd., No. 9, 1927, p. 1143) relate the results of their experiments in the subcutaneous injection of certain oils and oily combinations into various animals, both vegetable and animal oils and oils with different substances in solution, in combination, and in suspension, being used. These workers found that the absorption of oil occurs very slowly, and is complete only after several months, the absorption being slower with vegetable than with animal

oils. The injection of oil causes a very marked histological reaction in the hypodermic connective tissue, an encystment of each oil droplet occurring, and the cyst walls contain numerous mononucleated cells, which seem to play an active part. This reaction is accompanied by chemical changes in the oil, which becomes acidified, a local digestion of the oil occurring with the liberation of fatty acids. The absorption of substances in solution varies with the substance, sudan and chlorophyll persisting *in situ* after the disappearance of the oil, while camphor was absorbed in some hours and iodoform in a few days. In the case of substances in combination with oil, such as iodine, there was a slow destruction of the oil and a tardy resolution of the substance itself, this depending, not on the quantity of oil or drug injected, but on the activity of the tissues, which varied with the individual. As regards substances such as mercury and bismuth in suspension, L. Binet and Fleury have found that the oil undergoes saponification, and Picon has suggested that such saponification is the basis of the accidents following bismuth injections. Experiments *in vitro* have proved that a mixture of a neutral oil and fatty acids in the presence of certain bismuth salts, such as the hydroxide, results in saponification, while other salts, such as the carbonate, cause no such reaction. The present authors confirm these findings, and assert that only such salts should be used for oily injections as are incapable of combining with the fatty acids formed in the course of the absorption of the oil.

### 379. The Leucocyte Picture in Surgical Diseases.

M. SIEBNER (Deut. Zeit. f. Chir., February, 1928, p. 318) states that examination of the blood picture may yield valuable information, especially in the following groups of diseases. (1) Acute osteomyelitis and acute abdominal disease, such as appendicitis, pancreatitis, cholecystitis, and cholangitis, which show leucocytosis, neutrophilia, eosinophilia, and a displacement to the left. (2) Localized suppuration, such as cerebral, diaphragmatic, or perinephritic abscesses, and especially circumscribed peritoneal abscesses, after diseases of the stomach, gall-bladder, and appendix, infected wounds, fractures, and haematomata. Such cases show hyperleucocytosis, absence of eosinophilia, and neutrophilia at the expense of the lymphocytes. Chronic suppuration, as a rule, shows only moderate or slight leucocytosis, and a characteristic feature in such cases is the presence of degenerated neutrophils. (3) Simple catarrhal inflammation of the appendix, chronic cholecystitis, chronic peritonitis or pleurisy, extensive thrombophlebitis, recent fractures, and haematomata. In such cases there is only a slight leucocytosis with a normal or only slightly diminished number of lymphocytes.

### 380. The Chloride Content of the Cerebro-spinal Fluid in Tuberculous Meningitis.

M. LÉVY-BRUHL and YVONNE GARREAU (C. R. Soc. de Biologie, February 24th, 1928, p. 487) draw attention to the importance of estimating the chloride content of the cerebro-spinal fluid in the diagnosis of tuberculous meningitis. Following Mestrezat, they consider that the normal content is 0.73 to 0.74 per cent.; that in tuberculous meningitis it falls below 0.63 per cent. and is generally between 0.5 and 0.6 per cent., while in other meningeal affections it is generally between 0.65 and 0.7 per cent. In cases of subacute tuberculous meningitis, in which the chloride content may be 0.6 to 0.65 per cent., the differential diagnosis from other meningeal infections is best made by a cytological examination; in tuberculous meningitis nearly all the cells are lymphocytes, while in other infections most are polymorphonuclears. The authors record eleven cases of meningitis or meningoencephalitis, in which the value of the chloride test in picking out the tuberculous from the non-tuberculous cases is exemplified.

### 381. Bacterial Flora of Periapical Infections.

R. OTTOLENGHI (Giorn. di Batteriol. e Immunol., February, 1928, p. 114) has examined the pulp of 100 dead teeth. Previous workers have obtained positive cultures from 50 per cent. or more of such teeth, the predominant organism being a streptococcus, not infrequently accompanied by a staphylococcus. The author's procedure was to remove the tooth as aseptically as possible, to cut off the apex, and to drop it into broth. Subsequently cultures were made on different media, and were incubated aerobically and anaerobically. Positive cultures were obtained in 43 per cent. of cases. The organisms recovered were non-haemolytic streptococci in 15 per cent., *Streptococcus viridans* in 8 per cent., haemolytic streptococci in 2 per cent., staphylococci in 6 per cent., the enterococcus in 2 per cent., unclassified spore-bearing bacilli in 4 per cent., and pneumococcus Types I, II, III, and IV, *B. acidophilus*, and *B. coli* each in 1 per cent. Bacilli of the obligatory anaerobic type were never encountered.

### Medicine.

382.

#### Hyperpiesis.

E. B. GUNSON (*New Zealand Med. Journ.*, February, 1928, p. 1) emphasizes the fact that hyperpiesis is now widely recognized as a separate clinical entity which may or may not be associated with cardio-vascular or renal disease. He finds that, on analysis of 500 consecutive medical cases, 113 have systolic blood pressure readings of 170 mm. of mercury or over, in the absence of renal or valvular heart disease, and he considers these cases from the standpoint of systolic blood pressure readings in relation to symptoms and clinical findings. More or less equal numbers of both sexes are included in the total of 113, the ages averaging 52. Etiological factors are: hereditary tendency, worry, septic foci, excessive and faulty diet, and intestinal toxæmia. Although hyperpiesis occurs without symptoms, the most diverse manifestations may appear from impairment of the various bodily functions. Ten cases are described to demonstrate the common symptoms and the pressure changes resulting from treatment. General weakness, breathlessness, palpitation, and tightness in the chest on exertion, tinnitus, headache, giddiness after effort, flatulence, and epigastric discomfort are among the symptoms most frequently noted. The author regards rest as the first essential in treatment; worry and anxiety must be eliminated as far as possible. Any benefit resulting from dieting is more often due to general moderation than to restriction of meat or salt-containing foods. Digestive disturbances may be largely avoided by reduction of the carbohydrates and the avoidance of fluid at meal times. It is remarked that a too prolonged reduction in diet sometimes results in anæmia. Bromides, nitrates, and digitalis are recommended, the latter especially where elevation of blood pressure and return of symptoms have followed initial improvement. In most patients the greatest subjective improvement follows moderate blood pressure reduction, the level still remaining rather above normal.

383.

#### Typhoid Meningitis.

P. S. DUKAKIS (*Journ. Amer. Med. Assoc.*, December 31st, 1927, p. 2257) concludes that meningitis is a rare complication of typhoid, since only 33 cases have been reported. Among 2,768 cases of typhoid fever at the Johns Hopkins Hospital there were only 5 cases of meningitis. A study of the literature shows that only 30 cases of meningitis due to various causes have been reported in infants under 3 months old, the great majority being due in order of frequency to *B. coli*, streptococci, meningococci, pneumococci, and the tubercle bacillus. There was only one case of paratyphoid meningitis in children under 1 year, the patient being aged 7 months. Dukakis reports the case of a male infant, aged 2 months, breast fed, whose symptoms were regurgitation of its feeds, fever, bulging fontanelle, and slight nuchal rigidity; 5 c.cm. of opalescent fluid was obtained by lumbar puncture, and 25 c.cm. by cisterna punctura. Autimenogococcus serum was given intrathecally and intracranially. Death, preceded by optic neuritis, convulsions, and head retraction, occurred on the seventeenth day of disease. There was no necropsy. *B. typhosus* was recovered from the cerebro-spinal fluid. The Widal test was positive in the mother and typhoid bacilli were found in the stools.

#### 384. The Increased Incidence of Aortic and Cerebro-spinal Syphilis.

A. WOLDRICH (*Wien. Arch. f. innere Med.*, February 3rd, 1928, p. 141) states that there has been a recent increase in cerebro-spinal syphilis and syphilitic aortitis, though most of the smaller European States show a general decline in primary syphilis since 1924. Occasional decreases in the numbers of cases have been observed in recent times. After the Franco-Prussian war it was noted that the number of infected persons declined; this was attributed to a large increase in the marriage rate and more stringent control of prostitution. In contrast with the decrease in primary syphilis, parasyphilis has shown a continuous increase. It is generally admitted that among the less civilized races takes dorsalis and general paralysis seldom occur, while tertiary syphilides and gummata of the bones are more frequent; in the more civilized communities parasyphilis is always more prevalent. This difference has been variously attributed to strains of spirochaetes having special affinity for the nervous system, to degeneration of the civilized races, to a higher power of resist-

ance of native races, and to the evil influences of civilization and war injuries. Woldrich traces a parallelism between the incidence of cerebro-spinal syphilis and aortic syphilis, and states that after the year 1918-19 there was a great rise in the incidence of both until 1924. Since that date there has been a considerable fall in the curve of cerebro-spinal syphilis incidence, while that of aortic disease has remained almost stationary. Tables show also that cases of cerebro-spinal syphilis were three times as numerous in 1924 as in 1904, while those of syphilitic aortitis were fifteen times as numerous in 1924 as in 1904. Woldrich finds that in Czechoslovakia the increase of aortic and cerebro-spinal parasyphilis during recent years is undeniable. It commenced in the years 1918-19, but, assuming that the average incubation period of parasyphilis is fifteen years, the present remarkable increase is due to infection occurring in the quinquennium 1910-15, and is contemporaneous with the commencement of salvarsan treatment. The author adds that the prevention of parasyphilis can be secured only by systematic efficient treatment of all cases of syphilis in the early stages of the disease.

385.

#### Erythema Nodosum.

F. LO PRESTI-SEMINERIO (*Stadium*, January 20th, 1928, p. 12) reports three cases of erythema nodosum in young children, and discusses its etiology. In the first two patients, a brother and sister, the Pirquet reaction was strongly positive, and in one there was some evidence of hilus disease. The third patient gave no evidence of any other disease. The author believes that erythema nodosum is a specific infection, probably due to some filterable virus, and often having some relation to tuberculosis. In each of his cases the tonsils were hypertrophied, but no mention is made of any rheumatic infection.

### Surgery.

386.

#### The Incidence of Cancer.

REVIEWING the present position of certain cancer problems, M. GREENWOOD (*Cancer Review*, March, 1928, p. 97) states that the incomplete method of recording statistics followed in many countries renders difficult the obtaining of reliable information on this subject, but certain facts have emerged from this study. There has certainly been no decrease, and probably an increase, in the real mortality rate, but there is an indication that this increase is slowing down. Improved diagnosis is partly responsible for this apparent increase. The mortality rate is no longer considered to be higher in women than in men. The greater liability to a fatal termination of uterine cancer depends on injury to the cervix during the first labour, and the risks do not increase with the number of children born. Mammary carcinoma appears to be more frequent among unmarried women, and women who develop cancer seem to be less fertile; therefore, the non-specific factor involved may be the absence of a normal stimulus. The most prosperous class socially has the lowest mortality rate, and this differentiation has been found to be confined to certain sites, including the alimentary tract, skin, and larynx; this suggests that the poorer members of the population are exposed to some irritant or irritants the action of which does not reach the internal organs and cannot pass down the digestive tract below the stomach. The belief that a meat diet predisposes to cancer has not been confirmed. The results of treatment, especially as regards the breast and uterus, show that early radical operation is a much more hopeful procedure than is generally realized, and may give an average prolongation of life of more than ten years. There is also satisfactory evidence that radiology can compete satisfactorily with the knife in the treatment of cancer, and Greenwood believes that sufficient advantage of this method is not yet taken in this country. Adequate information is not yet available as to the influence of race, civilization, locality, and occupation on the incidence of cancer.

387.

#### Cervical Ribs.

G. PACETTO (*Arch. Ital. di Chir.*, January, 1928, p. 375) reports five cases of the above condition and discusses the subject generally. He states that the supernumerary rib may be associated with hypertrophy of the transverse process, or this hypertrophy may be the sole anomaly, as was the case in 56 out of 70 cases of cervical anomalies collected by Cronzon. Cervical ribs are usually bilateral, but, owing

to the fact that the condition is generally much more marked on one side, so far as signs and symptoms are concerned they appear to be unilateral; they occur more often in young women than in men. They may give rise to local physical signs not to disturbances of the circulation or of the nerves, due to pressure; motor disturbances are more rare than changes in sensation. Probably affections of the sympathetic system due to pressure are more common than is usually believed. When symptoms arise they do not necessarily persist, but may cease when the immediately exciting cause disappears; Puccetto remarks that, bearing this in mind, surgical intervention should not be hurried. He adds that it is said that cervical ribs or hypertrophy of the transverse process may be seen in 10 per cent. of the population, but the number of persons in whom this condition produces symptoms is very much less, and still smaller is the number of those who require surgical treatment for it. The possibility of anomalies in the first rib or transverse process of the first dorsal vertebra should also be borne in mind. The author appends an extensive bibliography of recent literature on the subject.

### 388. Aneurysm of the Splenic Artery.

GOULLIQUET (*Bull. et Mem. Soc. Nat. de Chir.*, March 17th, 1928, p. 402) records an unusual case of aneurysm of the splenic artery treated by removal of the sac. In this case the condition was diagnosed as a cyst of the pancreas, and its real nature was only discovered at operation. The aneurysm was successfully removed after ligation of the splenic artery, and the patient made a satisfactory recovery. Aneurysms of this vessel are said to occur about equally in men and in women. Syphilis is not regarded as of any importance in the etiology, and in no case does the diagnosis appear to have been made before operation. Trauma as a cause has been noted in a number of cases, either due to a gunshot wound or abdominal injury. The treatment of these cases is entirely surgical, and cure is not possible by any other means. Simple removal of the sac should be performed, but if this is impossible the aneurysm, together with the spleen, should be excised. This latter procedure will be necessary where the aneurysm is situated in a terminal branch of the splenic artery. Ligation of the artery alone should be performed if no other procedure appears possible.

### 389. Carcinoma of Prostate and Bladder.

B. S. BARRINGER (*New England Journ. Med.*, March 8th, 1928, p. 117) considers that cases of extensive prostatic carcinoma should not be subjected to major operations if it is possible to cope with the disease by radium, x rays, or a modified punch operation under local or spinal anaesthesia. It is shown by classifying the duration of life of 202 consecutive cases that in only 15 per cent. was there any length of life after the first examination, and only a few were benefited by any treatment. The operation should be followed by persistent radiation of the prostatic bed and of the lymphatics around the seminal vesicles; for those advanced cases with urinary retention some minor procedure should be adopted, since at least half of the patients will not survive for a year. In considering carcinoma of the bladder, of 20 cases of papillary carcinoma 75 per cent., and of 51 cases of infiltrating carcinoma 35 per cent., were cancer-free as long as observed. These included all cases in which the growth was small enough to be controlled intravesically and all those with radium implanted suprapubically. In 94 suprapubic implantations of radium the mortality was slightly over 3 per cent., compared with a mortality of between 10 and 20 per cent. for the operative removal of carcinoma of the bladder; this indicated that even if radium implantation was not more effective than operative removal a number of lives could be saved by its use. In Barringer's experience a large and increasing number of such cases are being controlled by the cystoscopic applications of radium, but the suprapubic operation is advised for practitioners who are not experienced in the use of radium, or when for any reason there is doubt as to the control of a tumour.

### 390. Gangrene of the Genitals.

J. BEJARANO and M. HOMBRÍA (*Arch. de med., cir. y esp.*, February 25th, 1928, p. 279) record a case in a man, aged 43, who, shortly after the crisis of lobar pneumonia, developed gangrene of the scrotum. Rapid recovery followed injection of 20 c.c.m. of a polyvalent antigangrenous serum consisting of a mixture of anti-vibrio, anti-perfringens, anti-oedematisans, and anti-histolyticus serums. *B. proteus* and *B. sporogenes* were grown from the lesions, and the patient's serum agglutinated *B. proteus* in 1 in 150 and *B. sporogenes* in 1 in 100 dilutions. Inoculation of guinea-pigs with *B. proteus* and *B. sporogenes* produced destructive lesions of a gangrenous type, which did not follow inoculation of either of these organisms separately.

## Therapeutics.

### 391. Tannic Acid Treatment for Burns.

S. BARLING (*Birmingham Med. Rev.*, March, 1928, p. 58) observes that in many cases of burns patients who survive the initial shock succumb later in consequence of absorption of toxins produced by the breaking down of the stable proteins of the damaged tissues. This absorption commences within a few hours after the burn, reaches its maximum after the second or third day, and death usually occurs at the end of the first week. Furthermore, burns, as generally treated, almost always become septic, such sepsis being inevitable while dead or damaged tissue is present to provide a soil for the growth of bacteria. The chief clinical symptoms of severe burns are elevation of temperature and pulse rate, restlessness, cyanosis, coma or convulsions, rapid respirations, and cold extremities. Treatment should be both local and general. Locally, toxic absorption and septic infection must be prevented, or at least limited, so far as possible. Since excision of the whole of the injured tissues is, as a rule, impracticable, these aims are best attained by applying coagulants, which fix the tissues and render the broken-down elements insoluble. Absolute alcohol and solutions of picric and tannic acids have been tried, the least objectionable being tannic acid. It is non-toxic and rapidly transforms the damaged tissues into a brown, leathery coagulum, which is insensitively, protects the underlying tissues, resists absorption, and is an unsuitable nidus for bacteria. Shock, if severe, should be first treated, local treatment being postponed for a few hours. Light ether anaesthesia may advantageously be used during the first dressing. The skin should be cleansed with soap and water, then with a 10 per cent. solution of sodium bicarbonate, followed by swabbing with ether, the opening of blisters, and the removal of loose cuticle. The burnt area is then sprayed with a 2½ per cent. aqueous solution of tannic acid, dried by a stream of warm air, and protected from pressure. The spraying is repeated hourly for the first eight or twelve hours, when the coagulum will be formed. Any fresh blisters should be opened and sprayed, as should also any moist areas. To avoid injury to the eyes, nose, and mouth in face burns, a 5 per cent. tannic acid ointment may be used instead of the spray. As the solution deteriorates with keeping, it should be freshly made every twenty-four hours. General treatment must provide for the neutralization or removal of toxins and the replacement of lost salts and fluids. Liquids should be given freely by the mouth and normal saline solution by rectoclysis or subcutaneously. Alkalis should be administered to increase the alkaline reserve, and in very severe cases exsanguination transfusion may be desirable, the blood of the donor being introduced into one vein while the patient's blood is withdrawn from another.

### 392. Scarlet Fever treated by the Dick Antitoxin.

L. BIDOLI (*Studium*, January 20th, 1928, p. 6) gave to 51 patients with scarlet fever intramuscular injections of Dick antitoxin; as controls he treated 54 cases on ordinary lines. In selecting the cases for injection preference was given to the more severe cases, which made the good results of the injections all the more striking. The usual dose of the serum was 25 c.c.m. each day for the first three days. Improvement in all the main symptoms soon followed, and no serious anaphylactic complications were noted. The duration of the rash was not appreciably affected, but patients treated by injections were able to leave the hospital five or six days before the controls, although the latter were the milder cases. As regards complications, rhinitis was present in 14 per cent. of the controls, as against 4.5 per cent. in the serum cases, and otitis in 9 per cent., against 20 per cent.; the incidence of mastoid trouble was about the same in both series, but there were no suppurative glands in the serum cases, as contrasted with 10 per cent. in the controls. The nephritis cases were about equal, but albuminuria occurred in 27 per cent. of the serum cases, as compared with 15 per cent. in the controls. There were three deaths among the control cases and none in the serum group.

### 393. Gold Salts in Cutaneous Tuberculous Affections.

JEANSELME and R. BURNIER (*Journ. de Méd. et de Chir. Prat.*, February 10th, 1928, p. 77) give an account of the treatment of cutaneous tuberculosis by gold salts, using a French preparation, erisalbine, closely resembling saucorysin. On the whole the improvement was very marked, and the best results were obtained with cases of erythematous lupus. Erisalbine is described as a white crystalline salt readily soluble in water. It is supplied in ampoules allowing a dosage of 0.05 to 1 gram. It is dissolved in distilled water immediately before use and injected intravenously. The

first injection consists of 0.10 gram, followed four days later by one of 0.25 gram. After this two injections of 0.25 gram are given each week up to twenty injections. Certain phenomena of intolerance may be exhibited—namely, albuminuria, nausea and vomiting, rise of temperature, cough, neuralgic pains, loss of weight, and stomatitis. Cutaneous complications are said to be the most frequent and the most serious. Of 32 cases of erythematous lupus localized on the face there were 20 complete cures, 7 improved, and 5 failures. By complete cure is meant the total disappearance of infiltration, redness, and keratinization. In some cases the skin became quite normal, and it was impossible to say where the lupus had been. In others a brownish pigmentation or slight scarring remained, but these were far less disfiguring than the original lupus. In obstinate cases after twenty injections the patients were given a month's rest before another series of injections was started. In four cases recurrence was noted, but this rapidly yielded to a second course of treatment.

## Neurology and Psychology.

### 394. Myasthenia Gravis.

J. M. NIELSEN and P. ROTH (*Journ. Nerv. and Ment. Dis.*, January, 1928, p. 32) summarize the hypotheses of various writers as to the pathology of this relatively rare disease. Jolly has demonstrated his myasthenic reaction (rapid fatigue of faradic irritability with unimpaired galvanic irritability), which proves the presence of organic changes. Among other observers, Weigert has described cell infiltrations of the muscles, which he regarded as metastases from thymic lymphosarcoma. Starr has noted pathological changes in the thymus in 28 per cent. of 250 necropsies, and Jelliffe believes that the cause lies in the vegetative nervous system. The present authors report three cases of myasthenia gravis, which, showing many differences, present a few salient points for comparison. One patient was a woman, aged 34, who presented a poorly developed musculature in general, with evidence of involvement of the bowels, a history of sexual excesses, and severe psychic trauma. The second patient, a married woman, aged 25, had given birth to a healthy child five months previously; she had a very low basal metabolic rate with evidence of myxoedema and of endocrine dysfunction with involvement of the bowel. The third patient, a man aged 36, had a poor musculature, and there were signs of syphilis of the central nervous system. The three patients had the typical onset and development of myasthenia gravis, and all showed Jolly's reaction. The authors maintain that the sexual excesses, myxoedema, syphilis, and psychic trauma are coincidences and not causative factors. They assert that myasthenia gravis seems to occur in persons with small or flabby muscles in general, and that the intestinal walls are impaired as is the voluntary musculature. Jolly's reaction is not necessarily present in all the muscles at any time. It was absent during remissions in two of the cases (the third was not tested), and was present only in the weakest muscles in one case. Strychnine seems to have little or no influence on the course of the disease. The basal metabolic rate is normal, and the exhaustion is probably of neuro-muscular origin.

### 395. Polyneuritis due to Mumps.

W. S. COLLENS and M. A. RABINOWITZ (*Arch. Intern. Med.*, January 15th, 1928, p. 61) report a case of polyneuritic quadriplegia with bilateral facial paralysis and meningitis complicating epidemic parotitis. A review of the literature showed that the characteristics of parotitic quadriplegia were flaccid paralysis of the extremities with loss of deep and superficial reflexes, slight sensory disorders, and deep disturbances such as those of the joint and vibratory senses. Complete recovery was the rule. The absence of abdominal reflexes, the presence of meningeal signs, and the few sensory manifestations with predominatingly motor phenomena point to there being some involvement of the cord in addition to the polyneuritis. The authors' patient was a man, aged 29, who, after a mild attack of epidemic parotitis, developed, one week from the onset, a left orchitis which resulted in atrophy. A fortnight later he complained of weakness in his legs, and was unable to stand; within two days he was unable to sit up or roll over in bed, and had difficulty with food owing to complete bilateral upper and lower facial paralysis, all the other cranial nerves being uninvolved. His neck was rigid, with his head in slight opisthotonos; he was unable to move his head or extremities. There was complete parietic quadriplegia and a marked bilateral Kernig sign; all the superficial, deep, and plantar reflexes were absent. Twenty-four hours later paraesthesia

of the feet developed, with tingling and burning sensations and hyperaesthesia of the arms, legs, hands, and feet, and loss of joint and vibratory sense. A week later the symptoms began to improve, the progress being more rapid after treatment with strychnine sulphate, 1/30 grain, three times a day; the motor signs improved more rapidly than the sensory. Four weeks after the onset of the paralysis he was able to stand with assistance and maintain quadriceps extension for thirty seconds, and his right facial power was returning to normal, though the deep reflexes and joint sense were still absent. Eleven weeks later all sensory, motor, and reflex phenomena were normal and he was discharged cured. All the reported cases showed quadriplegic manifestations, but varied in the nature of cerebral nerve involvement. This type of polyneuritis is said to be usually of infectious origin, resembling that complicating other infectious diseases.

### 396. Hemiplegia Associated with Extensive Nacvus and Mental Defect.

H. J. HUGO (*Journ. Med. Assoc. South Africa*, October 22nd, 1927, p. 534) refers to Brushfield and Wyatt's case of hemiplegia associated with nacvus and mental defect (*Epitome*, August 27th, 1927, para. 178), and reports an additional case of the same condition in a female idiot, aged 7, who was destructive, and unable to walk, speak, feed, or tend herself in any way. She was well nourished physically, but very undersized; she had epileptic seizures, the paroxysms being very severe. There was an extensive cavernous nacvus haemangioma over the right side of the neck from about the upper border of the mandible to the upper margin of the clavicle, which involved the upper and lower lips. The tumour increased in size during two years, and almost completely occluded the nostrils, but there was no haemorrhage from it. The left arm and both legs were paralysed, with a slight degree of atrophy of the muscles. The child died from status epilepticus, and at the necropsy vascular tumours, ranging in size from a pin's head to a pea, were found in all the brain ventricles, and similar growths were found in the kidneys and the liver; the brain showed scattered patches of sclerosis. It was concluded that the vascular tumours in the brain and internal organs were endotheliomata, probably secondary to the skin tumour. (Reference was made to another case of this condition, recorded by Brushfield and Wyatt, in the *Epitome* of January 28th, 1928, para. 99).

## Obstetrics and Gynaecology.

### 397. Uterine Pregnancy following Bilateral Salpingectomy for Tubal Pregnancy.

W. ZANGEMEISTER (*Zentralbl. f. Gynäk.*, February 18th, 1928, p. 411) describes the case of a woman, aged 24, who in 1927 complained of weakness, sickness, and pains in the back, and expressed fear of premature cessation of the menses. In 1925 the gravid left tube had been removed, but not the left ovary; in 1926 the right adnexa had been excised for right tubal gestation, and ventral fixation done. Subsequently the periods had become less, and the last two had been missed altogether. Examination showed a two months' uterine pregnancy; three days later abortion occurred and placental remnants were demonstrated microscopically in the fragments removed by curetting. About 200 cases have been published of right tubal pregnancies after operation for left, or vice versa; tubal gestation on the other side, it is said, may be expected to occur in about 5 per cent. of those operated on for tubal pregnancy—that is, in about one-sixth of those who become pregnant after such an operation. About 21 cases have been described in which tubal pregnancy has been repeated on the same side, occurring in fragments of tube left laterally or mesially, or in the interstitial part; to prevent such occurrences a wedge-shaped severance of tube and uterus has been recommended, but that this procedure is not necessarily effective is shown by Küstner's two observations of uterine pregnancy following wedge excision of both tubes for the purpose of sterilization.

### 398. Primary Abdominal Pregnancy.

E. R. FURGASON (*Journ. Amer. Med. Assoc.*, February 11th, 1928, p. 436) reports a case of what he considers to have been definitely a primary abdominal pregnancy in which the foetus was carried for ten months after the date of confinement. Caesarean section was performed, and the foetus was found in a large sac, completely filling the abdominal cavity, and adherent to the abdominal wall in front, to the transverse colon above and behind to the posterior abdominal wall, and to the small intestine below. So completely was the transverse colon adherent that it could not have been separated from the sac without destroying the intestinal blood supply.

The placenta had undergone calcification and was still adherent to the wall of the sac, the thickness of which was almost that of a normal uterus; there were no adhesions to the uterus. Only a small portion of the sac could be removed, but the patient made a good recovery and was able to leave the hospital three weeks after the operation. Ferguson comments on the confusion caused in this case by the re-establishment of normal menstruation at full term, and concludes that it is advisable to open the abdomen whenever there is such a history. The final diagnosis depended on vaginal examinations, confirmed by the use of x-rays, and it is suggested that both these procedures should be utilized more frequently when there is any doubt about the condition of the pregnancy.

### 393. Sequels of Radiation of the Ovaries.

H. MARTIUS (*Zentralbl. f. Gynäk.*, October 8th, 1927, p. 2601) discusses the possibility of the ovum being damaged in radiation of the ovaries. Weak radiation, in which the dose is insufficient to prevent ovulation, has been used in pelvic inflammations and with varying results, the best occurring in gonococcal infection of the adnexa, in puerperal parametritis, and in tuberculosis of the female genital tract. Martius uses it only when future pregnancy is already unlikely, as in two-sided infectious and tuberculosis, since it is impossible to regulate the dose so as to be sure of avoiding interference with ovulation. Weak radiation of the ovary is used in disorders of menstruation and sterility; its action is on the follicles, and if the dose is to be effective it risks damaging them. The clinical results are uncertain, and similar benefit follows radiation of the endocrine glands and diathermy. Martius thinks that it is only justifiable in polymenorrhoea and amenorrhoea of ovarian origin after medical treatment has been exhausted and surgical intervention is not possible. Stronger radiation doses prevent ripening of the follicles either permanently or temporarily; pregnancy may occur before the onset of the radiation amenorrhoea, and if so the child is usually damaged. It is advised that patients should avoid pregnancy for four months after radiation, and the author does not advise these larger doses while there is any prospect of pregnancy. When radiation is applied in order to promote temporary sterilization the usefulness in young women depends on the possibility of future pregnancy being preserved; there is always a risk of the induced sterility being permanent, or, if conception occurs subsequently, of the offspring being damaged. It should therefore only be used where there is no likelihood of future pregnancy, or where the radiation is confined to one side only. Martius deprecates the prevailing idea that radiation of the ovaries has no bad effects on the offspring, but he thinks that in some cases it may be worth while to disregard the progeny for the sake of the immediate benefit to the mother.

## Pathology.

### 400. *Leptospira icteroides* and *Leptospira icterohaemorrhagiae*.

E. MARTINI (*Centralbl. f. Bakt.*, February 15th, 1928, p. 402) has made some comparative observations on the spirochaetes of yellow fever and of Weil's disease. From experimentally infected guinea-pigs cultures of the heart's blood, liver, and kidney juice were made on Unger mann's medium, which consists of rabbit's serum inactivated by heating to 60°C. for half an hour, and covered with a layer of paraffin. The author found it very important in the cultivation of *Leptospira icteroides* to make cultures from the animal at the height of the fever. Usually the temperature reaches its maximum at 40° to 41°C. between the fourth and seventh days; sometimes it is maintained at a high level for only a few hours, so that it is necessary to observe the animal carefully. A high temperature does not necessarily betoken a particularly severe attack of the disease; some of his animals have recovered, even after exhibiting a temperature of 41°C. and oror, and after suffering from typical jaundice. On the other hand, the animals may die, with all the usual symptoms of jaundice, skin haemorrhages, epistaxis, necroses in the liver, and calcium cylinders in the kidneys without ever showing a rise of temperature to 40°C. Guinea-pigs were inoculated every week with cultures of *L. icteroides*; the virus was recovered from the heart's blood and introduced afresh into other guinea-pigs. The effect of this passage was to reduce the virulence of the strain. After about three months animals ceased to die after inoculation; infection still occurred, and cultures were obtainable from the blood, but death did not result. During the succeeding months the virulence became even less, so that icterus was no longer produced; a high temperature, however, continued to follow inoculation, and the organisms could still be recovered at the height of the fever. The resistance of one strain of *L. icteroides* and one

strain of *L. icterohaemorrhagiae* was tested in various media. In Unger mann's medium the former lived up to three years, the latter up to two years and one month; in a medium consisting of one part of rabbit's serum (inactivated) and three parts of saline the former lived up to three and a half years, the latter up to six months. It would appear, therefore, that the life of *L. icteroides* in culture is very much greater than that of *L. icterohaemorrhagiae*. The author suggests this very high resistance of *L. icteroides* may explain the re-emergence of disease in human beings after a long inter-epidemic period.

401. R. BRUYNOGHE and J. CORNIL (*C. R. Soc. de Biologie*, March 2nd, 1928, p. 598) have endeavoured to find out whether *Leptospira icteroides* differs from *L. icterohaemorrhagiae*. A comparison was made between two strains of *L. icteroides*, one strain of *L. icterohaemorrhagiae*, and one strain of a saprophytic spirochaete isolated from water. These organisms were cultivated in a medium consisting of one part of rabbit's serum, one part of broth, and four parts of saline solution, covered with a layer of vaseline; they all grew well at 28°C., and morphologically appeared identical. Three immune serums were prepared by injecting rabbits with *L. icterohaemorrhagiae*, saprophytic spirochaetes, and one strain of *L. icteroides*. Two series of tests were made with these serums. In the first series mixtures of serum and antigen in varying dilutions were incubated at room temperature and examined under the ultramicroscope after three or four hours and again after fifteen hours. The anti-*L. icterohaemorrhagiae* serum was strongly lytic and weakly agglutinating; it acted equally well on its homologous strain and on the two strains of *L. icteroides*. Moreover, its action was not inhibited by heating to 56°C., which suggests that complement was not essential to the lysis. The anti-*L. icteroides* serum was more strongly agglutinating than lytic; it acted equally well on its two homologous strains and on the strain of *L. icterohaemorrhagiae*. Neither of these two serums had any effect on the saprophytic spirochaete. On the other hand, the serum prepared against the saprophytic strain agglutinated and lysed its own cultures, but had no effect on the cultures of *L. icteroides* or *L. icterohaemorrhagiae*. In the second series culture media were made up with the different serums. Media containing anti-*L. icteroides* or anti-*L. icterohaemorrhagiae* serum inhibited the growth of both *L. icteroides* and *L. icterohaemorrhagiae*, but permitted a normal development of the saprophytic spirochaete; whereas media containing serum prepared against the saprophytic strain had no inhibitory effect on *L. icteroides* or *L. icterohaemorrhagiae*, though inhibiting the growth of the saprophytic strain. From these experiments the authors conclude that *L. icteroides* and *L. icterohaemorrhagiae* are biologically identical, and that, considering the clinical differences between yellow fever and Weil's disease, the causative agent of yellow fever is still unknown.

### 402. Malarial Therapy as an Indirect Immunizing Process.

W. H. GOECKERMAN (*Amer. Journ. Med. Sci.*, February, 1928, p. 261) remarks that although the value of malarial inoculations in general paralysis has been fully established, no explanation of their action has been afforded by the various hypotheses propounded; he reports a case suggesting an unusual factor. A woman, aged 35, presented all the mental symptoms of general paresis, and such physical examination as was possible, together with the Wassermann and other tests, confirmed this diagnosis. A malarial inoculation was given, and after passing through the usual course the patient was discharged. Six weeks later she showed definite mental improvement, and no cutaneous lesions were noted. Quinine, but no antisyphilitic treatment, was continued at home. Five months after inoculation the mental and physical progress was remarkable, but, despite this, typical nodulo-ulcerative syphilides had appeared on the left thigh and right buttock, these having been noticed by the patient about two weeks previously. Bloch believes that the appearance of a late syphilide is evidence of an allergic state, or at least of partial immunity, and the work of Brown and Pearce indicates that the tissue defence reaction is caused by the *Treponema pallidum*. No cutaneous test is known that will demonstrate specific allergy in syphilis, and it is possible that the entire defence reaction, including that of the skin, is non-specific in this disease. Goeckerman believes that the late appearance of the syphilides, coupled with the striking mental and physical improvement, suggests that the malarial treatment re-established a partial immunity in which the skin played a definite part. The gradual rather than rapid improvement of the spinal fluid in this case, as in many others, further supports the theory that the mechanism of malarial treatment is, at least in part, explainable on the basis of a tissue reaction rather than of a direct spirochaetocidal effect.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 403. The Incidence of Visceral Syphilis.

F. REDLICH and P. STEINER (*Wien. Arch. f. innere Med.*, February 3rd, 1928, p. 163) comment on the fact that while there is an undoubted extension of syphilis as a result of the late war, the former predominance of syphilitic lesions of the skin, mucous membranes, and bones has been exchanged for a preponderance of syphilitic diseases of the nervous and circulatory systems. Moreover, during the last decade visceral syphilis has been much more common, coincidentally with the adoption of energetic mercurial and arsenobenzol treatment. The authors cite German and American statistics in support of this observation. They have observed 3,000 patients (1,400 men and 1,600 women) during the period 1923-26. Of the 1,400 males, 212 were syphilitic; of these, 82 admitted infection (5.8 per cent. of those under observation, and 38 per cent. of the syphilitic cases); 13 males who had been treated recently in the dermatological department had no symptoms of syphilis, although 6.1 per cent. had a positive Wassermann reaction. Among the 1,600 females only 194 were definitely syphilitic. Of these, 33 patients admitted infection (2 per cent. of the observed cases and 17 per cent. of the syphilitics); 3 patients showed no signs of syphilis, but had positive Wassermann reactions (1.55 per cent. of all patients). The authors draw the following conclusions. (1) Among 3,000 patients 406 (13.6 per cent.) were definitely syphilitic. Out of 1,400 males there were 212 cases (15.14 per cent.) and among 1,600 women there were 194 (12.2 per cent.) syphilitics. (2) Between the ages of 31 and 60 years 19.4 per cent. males and 15.1 per cent. females were syphilitic—that is, approximately every fifth man and every seventh woman had been infected. (3) The Wassermann reaction was positive in 10.23 per cent. of all patients under observation and a positive reaction without clinical symptoms occurred in 27 per cent.—that is, every tenth patient had a positive reaction, but 3 of these had no clinical evidence of syphilis. (4) Diseases of the central nervous system were present in 135 patients (4 per cent.). (5) Diseases of the circulatory system were found in 88 patients (2.9 per cent.); excluding patients under 40 years old, the percentage was raised to 5.4. Among the 3,000 cases 3 per cent. had syphilitic aortitis (21 per cent. of all syphilitic patients). These observations show the preponderance of syphilis of the circulatory and central nervous systems. The authors add that this great frequency of visceral syphilis necessitates the greatest attention being paid to the patient's previous history and to the Wassermann reaction. The authors agree that syphilis has lost its character as a skin disease and has become largely a disease of the circulatory and central nervous systems which demands most careful study.

### 404. The Temperature in Whooping-cough.

A. DUFOURT (*Journ. de Méd. de Lyon*, February 20th, 1928, p. 109) disputes the view of Cadet de Gassicourt that any considerable rise of temperature in whooping-cough indicates a pulmonary complication. During the catarrhal stage, as Bencht, West, and Troussan, among others, have pointed out, the temperature may be fairly high and irregular or simulate intermittent fever; with the advent of the paroxysmal stage a fall of temperature may occur. Occasionally, however, the temperature keeps up, or rises still higher. In the course of the paroxysmal stage sudden febrile attacks may develop without any obvious cause and of long or short duration. Dufourt records five cases in children aged from 6 months to 8 years, in which the temperature was of an inverted type and presented wide oscillations between the morning and evening record. In none of the cases was there a definite pulmonary lesion. Tuberculin tests were negative, and the subsequent favourable course in each case showed that tuberculosis was not responsible for the fever.

### 405. Diabetic Acidosis.

D. MCCARTHY (*Minnesota Med.*, March, 1928, p. 158) analyses twenty cases of diabetic acidosis and coma from the standpoint of symptomatology. Apart from the abnormalities in the urine, he regards the following signs as important: flushing of the face and singlish mentality; odour of acetone in the breath; increase in the depth and frequency of respiration—this sign, and dryness of the mouth, being always present. Other common manifestations are pain in the upper abdomen and vomiting; and decrease in the intraocular tension. The absence of this latter sign in a comatose patient who is

known to be a diabetic may prompt search for, and discovery of, a vascular lesion such as cerebral thrombosis, and so avert the danger of an unnecessary injection of insulin. A leucocytosis of 13,000 to 20,000 per c.mm. is a constant finding, but the numbers always return to normal on recovery from coma. The presence of such leucocytosis in association with abdominal pain and vomiting may lead to a mistaken diagnosis of an acute abdominal condition. For the general management of severe acidosis or coma the author considers reassurance, warmth, normal saline enemata, and the administration of fluids as the most important measures. Fluids should be given by the mouth if possible, or, failing this, by the rectum or subcutaneously. Gastric lavage is necessary if there is vomiting, and hypodermic injections of digitoxin are recommended until the patient is out of danger. The method of administration of insulin depends upon the degree of acidosis; if this is not severe the patient is given 8 oz. of milk and 10 to 20 units of insulin every four hours, the later doses of insulin being controlled by urine examination. In the more severe cases an initial dose of 30 units is given intravenously and repeated every two hours until the urine is sugar-free; the dose is then decreased and the patient begins to take milk or orange juice.

### 406. Transmission of Scarlet Fever by Books.

B. FEJGIN (*C. R. Soc. de Biologie*, January 20th, 1928, p. 118) examined cultures of the pages of the books used by children suffering from scarlet fever, especially the corners of the pages, which were most likely to be contaminated by the patients' saliva, and isolated haemolytic streptococci either in pure culture or in association with saprophytic organisms, especially *Staphylococcus albus*. Further tests showed that the streptococci were identical with the causal organism of scarlet fever. The following two control tests were performed. Six books of healthy children who had never had scarlet fever were examined, and in none of them were scarlatinal streptococci found. A new book was contaminated with a broth culture of a scarlatinal streptococcus, with the result that cultures of the book taken at different intervals were positive for four to six weeks. Fejgin adds that the practical outcome of these investigations is that books handled by scarlet fever patients may harbour the causal organism and be responsible for the spread of the disease. Such books, therefore, should not be used for at least six weeks, and even after that period it would be best to disinfect them.

### 407. Musculo-spiral Paralysis following Injection of Quinine.

J. M. DE VILLAYERDE (*La Méd. Ibera*, February 18th, 1928, p. 173) records the case of a man, aged 33, who developed right musculo-spiral paralysis directly after subcutaneous injection of a solution of quinine for malaria in the outer aspect of the upper arm 5 or 6 cm. above the elbow. Three hypotheses may be suggested to explain the paralysis: (1) the neuritis was due to an infection; (2) it was caused by a direct lesion of the nerve by the point of the needle; (3) it was due to direct irritation of the nerve by the quinine. Infection could be excluded by the fact that the loss of power occurred immediately after the injection; moreover, there was no evidence of any local infection. It was hardly conceivable that the neuritis was of traumatic origin, since it was almost impossible for a lesion of such magnitude to be produced by the mere prick of a needle. In lumbar puncture one of the nerve cords of the cauda equina may be pricked by the point of the trocar, but the only effect is the occurrence of severe pain radiating to the foot, and no paralysis results. The most likely explanation is that the lesion of the musculo-spiral was produced by direct action of the drug on the fibres of the nerve. The prognosis in cases of local toxic neuritis is always very favourable, and rapid re-establishment of function follows. The possibility of proliferation of the connective tissue round the nerve must, however, be taken into account, since the fibrous tissue which is formed may cause compression of the nerve.

### 408. Immunization against Diphtheria with Virulent Cultures.

H. A. EBERHARD (*Deut. med. Woch.*, February 3rd, 1928, p. 181) states that Böhme in 1924 published a paper on active immunization against diphtheria by a vaccine composed of cultures of living virulent diphtheria bacilli. Since then Eberhard has also used the same method, with the following results. Inoculation was performed on 82 subjects, 37 of whom were small children, 13 school children, and 32 adults

between the ages of 20 and 40. The inoculations were made on the skin on the front of the thigh, the contents of a capillary tube being rubbed in without drawing much blood. Local reaction was usually slight, and constitutional disturbance was rare, or at most there was a slight rise of temperature. Healing occurred in most cases without redness of the skin or scab formation. In 54 cases the antitoxin content of the blood was determined before inoculation, and once or more afterwards. In 20 cases there was no change in titre in the first fortnight after inoculation. Although some patients showed an increase in the titre following inoculation, a considerable number of them showed no such rise. In any case, the method proved very inferior to that of toxin-antitoxin mixtures as regards the formation of antitoxin. Eberhard adds that the question must remain open as to how far formation of antitoxin is an indication of immunity.

#### 409. Clinical Significance of Gallop Rhythm.

P. D. WHITE (*Arch. Intern. Med.*, January, 1928, p. 1) records his observations on 100 patients with gallop rhythm, his conclusions being as follows. Gallop rhythm, which he defines as a rapid sequence of three heart sounds with each cardiac cycle, may be divided into four types—presystolic, systolic, protodiastolic, and mesodiastolic. The protodiastolic, which is the commonest, is probably due to the marked accentuation of the usually faint normal third heart sound. Gallop rhythm is almost invariably evidence of severe heart disease. No fewer than 45 of White's patients died within two years of the discovery of the sign, and 32 within six months. When last heard of a considerable number of the remainder were dead or seriously ill. Males were more often affected than females, in the proportion of 3 to 1. Gallop rhythm occurred in both young and old, but the average age was between 50 and 60, and 48 per cent. were between 60 and 70. In 16 patients under 30 it was more often associated with nephritis or mitral stenosis, and in the older patients with coronary aortitis. Congestive failure was the most outstanding feature, being present in at least 60 per cent. Angina pectoris was common (25 per cent.); cardiac asthma occurred in 14 cases. The heart rate was usually rapid, averaging about 100. The blood pressure varied, the systolic being between 100 and 150 mm. of mercury in 43 cases, between 150 and 200 in 35, over 200 in 19, and under 100 in 3. Pulsus alternans was found in 21 per cent. The heart was considerably enlarged in 60 per cent., definitely normal in only 6, and doubtful in 18. Valvular disease was uncommon. Electro-cardiograms were obtained in 64 cases, and only 2 were normal. Intraventricular block was the most common abnormality found (24 cases, or 38 per cent.), but atrioventricular block was surprisingly infrequent, being recorded in only 11 cases. Of the 17 cases tested, renal function was normal in 8 and abnormal in 9. Digitalis as a possible factor in the production of gallop rhythm could be eliminated, as in at least 32 cases none had been given, and in only 12 had a considerable amount been administered. Moreover, in some cases the gallop rhythm disappeared coincident with the improvement following rest and administration of digitalis.

## Surgery.

#### 410. Gastrectomy in Gastric Cancer.

X. DELORE and P. MALLET-GUY (*Paris Méd.*, March 17th, 1928, p. 254) emphasize the importance of early diagnosis if operation for gastric cancer is to be successful, and, while not denying the aids furnished by the laboratory and radiology, assert that clinical symptoms and the clinical sense are of equal, if not greater, importance in this respect. An exploratory operation is strongly advocated whenever carcinoma is suspected. After the age of 50 loss of appetite and emaciation are almost definite indications of cancer, and when unfeeling chronic affections, such as tuberculosis and nephritis, can be excluded, anorexia for fats and meats, with a progressive loss of weight and energy, is often the first sign of gastric cancer. Gastric symptoms are often limited to simple sensations of heaviness, gastric cramps, and discomfort after food. Except in stenosis, vomiting and haematemesis rarely occur early, though the vomit and stools should always be tested for occult blood. A slight, anaemic, yellowish tint of the skin often appears at an early stage, and blood counts and gastric intubation will afford valuable information. The authors believe that the classic hypothesis that an original seat of the tumour is of better prognosis is unfounded. Early diagnosis may be more difficult when the acuteness of the pain resembles that of ulcer. In the latter, though great emaciation is present, loss of energy is not so marked and the complexion remains clear. Change in the pains, their unusual persistence, and the disappearance

presence of a tumour. Resection of chronic gastric ulcers is strongly advised as a prophylaxis against cancer. In gastric carcinoma gastrectomy should be performed in preference to palliative operations, such as gastro-enterostomy. The authors do not attach much importance to the four factors usually considered as influencing prognosis—namely, stenosis of the pylorus, extension to the lymphatic system and neighbouring organs, and the microscopic and macroscopic anatomy of the cancer, though they consider colloid cancers to be particularly malignant. In many cases marked improvement and even temporary arrest have been noted after gastrectomy, life being prolonged from one to two years. The authors believe that a patient who has passed the third year in good health is almost certainly cured, and give six years as the extreme limit for the appearance of recurrences.

#### 411. Transcervical Fractures of the Femoral Neck.

A. CHENUT (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, February 25th, 1928, p. 145) remarks that it is indisputable that excellent results are obtained by bloodless treatment in cervico-trochanteric fractures of the neck of the femur, but that this is certainly not so in transcervical ones, and a case is reported in support of this view. The patient, a man aged 74, was admitted to hospital with such a fracture of the right femur. Bloodless treatment was instituted by means first of the Whitmann apparatus, and later of the plaster boot of Pareclier, and after five months the patient was discharged apparently cured. About two months later, on flexing the limb, intense pain was felt in the hip; after this walking became impossible, and the weight of the body could not be borne by the fractured limb. Chenut believes that the callus formed had not been ossified, even at the end of seven months, though it had become sufficiently solid to permit of walking for more than three months, and that in these transcervical fractures spontaneous ossification is very rarely realized. In such cases bloodless treatment should be employed only where other operative measures are contraindicated owing to the age, or the cardiac, renal, or general condition of the patient. Operation should be performed as soon as possible after the fracture in order to prevent the formation of pseudo-arthroses. Where bloodless treatment is deemed advisable Chenut strongly recommends the use of Pareclier's plaster boot with lateral wings. It is said to be tolerated much better than Whitmann's apparatus, is very simple and easy to apply, and keeps the limb in the desired position of forced internal rotation and abduction.

#### 412. Temporary Haemostasis in Abdominal Surgery.

L. MAYER (*Bulletin Médical*, February 26th, 1928, p. 564) believes that drainage after appendicectomies has become exceptional, and that many operators have abandoned tamponing after cholecystectomy; he emphasizes the difficulty in certain conditions of tying a deep vessel or excretory duct. He maintains that as satisfactory a haemostasis can be obtained by leaving clamps in position for a certain length of time, and the excellent results obtained by this technique in vaginal hysterectomy have encouraged him to try it in certain abdominal operations. Fourteen cases of such operations, including cholecystectomy, nephrectomy, and splenectomy, are reported in which this procedure was adopted with satisfactory results, secondary haemorrhage or any other untoward accident never occurring. This method occupies less time than tying, and is especially advantageous in cases where the poor general condition of the patient renders advisable a minimum duration of operation; it is also said to be expedient in cases, such as acute gangrenous cholecystitis, where the friability of the tissues renders the retention of sutures doubtful. Mayer uses a long, curved, mouse-toothed forceps clamp, seizes the vessels and duct concerned, and leaves the clamp in position for forty-eight hours. He adds that the clamp should be wrapped in gauze to avoid injury to the surrounding tissues, and should be withdrawn carefully and parallel with the axis of the incision.

#### Arthritis due to Foreign Bodies.

413. O. F. EHRENTHEIL (*Deut. Zeit. f. Chir.*, February, 1928, p. 409) states that this condition was first described in 1900 by Scultze, who distinguished two forms of arthritis of this kind, according as the foreign body was of metal or of wood. In the first form the symptoms are intermittent effusion into the joint, with pain and disturbance of function. When the joint is immobilized by a bandage the symptoms disappear, but recur when the joint is used again. The diagnosis in such cases is easily made by x rays. In the second form the symptoms are the same as in a fungating disease of the joint, with discharge of thin serous pus and fistulous openings with bluish-violet undermined edges. In such cases x rays do not help and the diagnosis can be made only by a careful consideration of the history, inspection of scars, palpation, and finally exploratory arthrotomy. Ehrentheil reports a case

In a girl aged 12 years, in whom the condition was first mistaken for tuberculous arthritis and treated accordingly by extension for three months. The correct diagnosis was then made by x-ray examination, which showed a needle in the left knee-joint. Complete recovery followed its removal.

#### 413. Köhler's Disease.

F. BENSO (*Rif. Med.*, February 20th, 1928, p. 179), who records two illustrative cases in a girl aged 5 and a boy aged 6 years respectively, states that Köhler in 1908 was the first to describe a painful condition of the tarsal scaphoid, usually unilateral and occurring between the fifth and ninth years, and characterized by delay in the development of the bone. The condition is rather rare, and not more than one hundred cases have been recorded. Boys between the ages of 5 and 10 years are chiefly affected. There is no example of hereditary transmission of the disease or of the occurrence of more than one case in a family. The symptoms are spontaneous pain in the dorsum of the foot, aggravated by walking and pressure on the tarsal region, which is slightly swollen, red, and hot. There is a slight degree of limping; passive movements of the foot are not restricted. There is sometimes atrophy of the calf. X rays show that the lesions are localized to the scaphoid, which is smaller than normal, especially in its antero-posterior diameter. The architecture is impossible to recognize, the cortex and spongy portion running together and the density being increased two- to four-fold. The course of the disease varies, but as a rule recovery ensues in a few months. Not infrequently the symptoms disappear after a few days' rest, and recovery of function is obtained in one or two months. Treatment, which is essentially conservative, should consist in immobilizing the foot by a suitable apparatus for a time ranging from one to six or seven months according to the severity of the case. As regards pathogenesis, Köhler's disease has been variously attributed to trauma, infections (especially tuberculosis and syphilis), endocrine disturbances, and late rickets.

#### 415. Malignant Tumours of the Testicle.

C. K. HIGGINS (*Annals of Surgery*, February, 1928, p. 263) remarks that most malignant tumours of the testis may be classified as teratomas, or mixed tumours, and spermatocytic tumours. Sarcoma of the testis is quite rare. Teratomas comprise over half the malignant conditions of the testis; they are very malignant and rapid in growth. These tumours are usually found between the ages of 20 and 50 years, but no age is exempt. There is often a history of trauma. Many cases are only seen after metastases are present; these may be found in the abdominal glands and also in the inguinal glands. Treatment has been tried by x rays, radium, Colley's fluid, orchidectomy, and radical operation. Higgins thinks that a radical operation should not be performed if enlargement of the glands can be recognized clinically. The prognosis after all forms of treatment is grave; it is most serious in the mixed tumours. Carcinomatous growths are the least malignant type. Higgins records twenty-three cases; six of the patients are still alive at varying periods after operation.

#### 416. Kaposi's Disease.

E. K. STRATTON (*Urol. and Cutan. Rev.*, February, 1928, p. 71) records a case, in a man aged 60, which clinically and microscopically corresponded to the rare disease known as Kaposi's multiple haemorrhagic sarcoma. The interesting features were (1) the development of a primary tumour on the scrotum at a spot where there had been severe pruritus ten years previously; (2) the appearance of similar tumours on the extremities—namely, the hands, feet, and ears after exposure to extreme cold; (3) the involvement of the right inguinal lymph glands; (4) no evidence of tumour formation in the viscera. The history of a primary lesion beginning at the site of a severe pruritus is suggestive of a specific micro-organism acting as the irritant. Winternitz and Noggs in 1910 reported a case associated with cirrhosis of the liver, and thought that metabolic products constituted the stimuli. Circulatory disturbances, such as exposure to severe cold, have been frequently recorded as a cause of Kaposi's disease, the explanation being that escaping blood provides the irritant substances causing endothelial proliferation.

#### 417. Injuries and Deaths from Boxing.

K. WOLFF (*Deut. Zeit. f. Chir.*, February, 1928, p. 379) states that the typical injury inflicted in boxing is metacarpal fracture, the following bones being affected in order of frequency: (1) head of first metacarpal; (2) bodies of second, fourth, and fifth metacarpals; (3) Bennett's fracture of the base of the first metacarpal; (4) fracture of the neck of the second and fifth metacarpal; (5) fracture of the body of the third metacarpal. Although many fatalities must have occurred in the brutal fights of past centuries, relatively few

cases have been recorded in recent years. In a series of 22 cases which have been reported since 1920 in Germany, where boxing was first introduced after the war by men who had been interned in England, evidence as the cause of death was available in only 13, and in only 9 for which boxing was responsible, subdural haemorrhage on one or both sides being the cause in 6, cerebral haemorrhage in 1, and fracture of the skull in 2. In view of the large number of boxing matches which have been held a total of 9 fatal cases is regarded as extremely small.

## Therapeutics.

#### 418. Protein Therapy in Leprosy.

N. A. DYCE SHARP (*Trans. Roy. Soc. Trop. Med. and Hyg.*, January, 1928, p. 305) believes that the essential feature in the treatment of advanced cases of leprosy is the degree of initial reaction. Any substance, therefore, which will result in a smart reaction in a leprosy individual will probably achieve a beneficial result apart from any specific action. The most suitable protein body to produce a shock is tinned milk prepared under the most hygienic circumstances and free from preservatives of any sort. The technique is as follows. The top of the tin is cleaned and a small hole made in it by a sterile nail; 2 or 3 c.c.m. of milk are then slowly drawn up into a 10 c.c.m. syringe and diluted with distilled water in a test tube, so that the strength of the dilution is 1 in 10. The standard dose of 0.5 c.c.m. of tinned milk is therefore contained in 5 c.c.m. of diluted milk. The reaction consists in a feeling of giddiness, which comes on within half a minute, followed in three or four minutes by marked respiratory distress and more or less severe precordial pain. Within five minutes of the injection there was always sharp pain in all the joints with severe frontal headache. General improvement followed in another five minutes, and usually within half an hour the patient was able to go home. A secondary reaction, shown by a rise of temperature to 103° to 104° F., would set in at night, and might recur for several nights. In every case complete relief from pains in the joints and bones and from formation occurred within twenty-four hours. At the end of forty-eight hours the temperature was usually normal, and there was almost complete freedom from pain, except in the septic ulcers. In the course of a week the skin lesions, including the perforating ulcers in the soles, showed a marked improvement. Relapses are apt to occur, when benefit may be derived from a second injection. In two of the twelve cases treated the injection was given into the buttocks. There was little, if any, immediate reaction, but when there was a smart febrile reaction a few hours later the end-results seemed to be the same. The author concludes that the treatment, though admittedly drastic and undoubtedly dangerous, seems to be specially applicable to the late and less hopeful forms of the disease.

#### 419. Quinidine in Coronary Thrombosis.

S. A. LEVINE and W. B. STEVENS (*Amer. Heart Journ.*, February, 1928, p. 253) describe the use of quinidine sulphate in coronary thrombosis complicated by ventricular tachycardia. This abnormal rhythm is not uncommon, and is in most cases the sequel of coronary occlusion. In many cases the tachycardia is transient, but, if it persists, the condition of the patient soon becomes extremely grave, as in a case reported. A man, aged 53, was admitted to hospital suffering from typical coronary thrombosis with persistent retrosternal pain, gallop rhythm, pyrexia, leucocytosis, and falling blood pressure. He continued to have some cardiac failure, but no other complication, until the fifteenth day in hospital, when the pulse rate was found to be 198, and an electro-cardiogram proved the presence of ventricular tachycardia. An intravenous injection of 5 grains of quinidine sulphate was given without effect. Four hours later 6 grains was given by the mouth, and on the next day 8 grains. Since the condition of the patient was deteriorating these daily doses were increased progressively to 18 grains, and then, four days from the inception of abnormal rhythm, it was shown by electrocardiography that occasional normal cardiac cycles were appearing. After two more doses of quinidine, each of 23 grains, the rhythm had become normal, apart from occasional ventricular extra-systoles. For the next six days doses of 15 grains were given four or five times a day, and then on withdrawal of the drug the pulse was slow and no irregularity recurred. Great improvement in the general condition of the patient coincided with the restoration of normal rhythm. The authors concur with the general hesitancy to use quinidine, but believe that its use is justified where the continuance of ventricular tachycardia is hastening a fatal issue. They comment also on the very large doses which were required in this case to produce the desired effect.

**420. Sodium Cinnamate in Pulmonary Tuberculosis.**

R. COURTOIS (*Le Scalpel*, February 11th, 1928, p. 141) discusses the treatment of pulmonary tuberculosis by sodium cinnamate, which has been used for more than twenty years at the sanatorium of La-Hulpe-Waterloo, from which the author has drawn his cases. Total statistics taken from a series of 200 unselected cases indicate that less than half of those treated were benefited at all, and that only some 12 per cent. were greatly improved. By arranging, however, all the cases in classes according to their lesions it is shown that the cinnamate treatment has had well-marked influence in certain types of cases, including the so-called ulcero-fibrous type, usually associated with normal or raised blood pressure, and tuberculous pleurisy which is not becoming quiescent under sanatorium treatment. The author has found that in cases of the ulcero-caseous type, cinnamate treatment does not give much hope, especially where the temperature is persistently high, nor is it useful in bronchitic cases. In early stages with a tendency to the ulcero-caseous type, as indicated by low blood pressure, cinnamate treatment may check the disease. Courtois has not used sodium cinnamate in any case unless sanatorium treatment alone had effected no improvement in two months. He gives a series of forty intravenous injections, ten with 1 per cent. solutions, ten with 2 per cent., and twenty with 5 per cent. The total amount of the drug used is not stated. In conclusion, the author claims that sodium cinnamate is the most important drug that can be used as an adjunct in the treatment of pulmonary tuberculosis; he recommends it strongly for cases seen in general practice where there is no great elevation of temperature and where sanatorium treatment is impracticable.

**421. Malarial Therapy in General Paralysis.**

H. A. BUNKER, Jun., and G. H. KIRBY (*Med. Journ. and Record*, February 15th, 1928, p. 173) describe their experience during four and a half years of the treatment of general paralysis by malaria, comprising observations on 156 unselected males in all stages of the disease with definite mental symptoms necessitating commitment to a mental hospital. At least 50 per cent. gave a definitely favourable response, even though in a third of them residual signs of previous cerebral tissue destruction precluded full clinical recovery. Discussing the permanence of the remission of mental symptoms obtained in those responding favourably to treatment the authors call attention to the fact that not only did complete remission occur in about one-third of the cases, but that in fourteen out of sixteen cases the remission has been maintained unaltered for at least three and a half to four and a half years. With reference to the type most likely to respond to treatment it was found that remission was good in 14 per cent. of the simple dementia type, whereas in the manic or hyperactive type 75 per cent. were definitely improved. The authors remark that by earlier treatment, before marked mental symptoms have appeared, much irreparable cerebral damage might be avoided, and they urge that advantage should be taken of a form of treatment which is remarkably effective against a disease which has largely resisted older methods of treatment. In just over one-fifth of the cases the Wassermann reaction in the spinal fluid became completely negative after treatment with malaria alone.

**Disease in Childhood.****422. Influenza in Infants.**

L. MOLL (*Wien. klin. Woch.*, November 24th, 1927, p. 1486) states that the organisms generally found in influenza in infants are the pneumococcus of Fraenkel, *Micrococcus catarrhalis*, *Streptococcus pyogenes*, and, much more rarely, Pfeiffer's influenza bacillus. In some epidemics a haemolytic streptococcus predominates. Two main forms of influenza occur in infants—the severe and the mild. In the severe or vasomotor type, commonest during the first three months of life, death may occur after only a couple of days' illness, with symptoms of severe general muscular weakness, pallor, rapid respiration, and general cyanosis, with occasional meningeal signs, such as vomiting, squint, and rigidity. Large areas of the lung are dull to percussion and a few crepitations may be audible, the liver is enlarged and soft, the heart may be dilated to the right, and the pulse small and accelerated; the temperature varies, and may be high or subnormal. Post-mortem examination frequently shows congestion of the liver, spleen, and the whole portal system, and the author ascribes this to vasomotor paralysis mainly affecting the splanchnic area; he thereby accounts for a part of the symptomatology of the disease in older children and adults as well. He also found, in co-operation with Luksch, that the suprarenal glands are congested and only contain

minimal amounts of adrenalin, but whether this is the cause of the paralysis or is a concomitant phenomenon is undecided. These pathological observations offer an explanation for the proved value of such vasomotor stimulants as adrenalin (1/2 c.cm. of 1 in 1,000 solution, subcutaneously) and caffeine (0.5 gram spread over two days orally, or 0.5 to 1 c.cm. of a 10 per cent. solution subcutaneously). In the milder form catarrhal symptoms predominate, often beginning in the nasopharynx and spreading to the larynx, trachea, and bronchi; if the lungs are affected it is generally the upper lobes. For the nasopharyngitis Moll advocates sweating treatment: 0.1 to 0.2 gram of aspirin may be given with comparatively large quantities of tea; sweating is also encouraged (though it must be carefully watched as it is not without risk) by a steam-tent constructed from an open umbrella covered with a sheet under which the mother sits holding the infant with a vessel of hot water at her feet. Locally one or two drops of adrenalin or 1 per cent. collargol solution are applied to each nostril. In cases with capillary bronchitis the condition of the gastro-intestinal tract is of particular importance, so that the absorption of nourishment may be adequate; in both breast- and bottle-fed infants a mixed diet of breast and cow's milk was found useful.

**423. Leukaemia in Childhood.**

W. K. HUNTER (*Glasgow Med. Journ.*, January, 1928, p. 1) classifies in five groups a series of twenty-two cases of leukaemia in childhood, observed over a period of twenty years. (1) One case of chronic lymphatic leukaemia with the white cell count rarely above normal, although the lymphocytes were absolutely and relatively increased; the glands all over the body, as well as the spleen, were enlarged. The case terminated fatally in two years. (2) Two cases of a more acute type of lymphatic leukaemia, with a duration of six weeks and fourteen weeks respectively. They each had a large mediastinal tumour with the histological characters of a lymphosarcoma. (3) Six cases of the most characteristic type of the disease, with a duration of from one to five and a half months. In most of them there was a pronounced anaemia, and in all a leucocytosis of from 13,000 to 300,000, mainly of a mononuclear, non-granular, primitive type of cell, now more generally regarded as a myeloblast rather than as a lymphoblast. (4) Five cases of leukaemia, or perhaps more correctly erythro-leukaemia, associated with pernicious anaemia. The difference between these cases and those in the third group is mainly one of degree, for several cases in the earlier group had also a number of nucleated red cells in the blood. (5) Eight cases of aleukemia; indeed, there was an actual leucopenia in almost all. In two cases the mononuclear cells seemed to be mainly myeloblasts, while in the other six it was regarded as a lymphocyte. Another feature of the group was the profound anaemia. Some haematologists would place the latter six cases among the aplastic anaemias; the author, however, inclines to the view that they are leukaemias. The pathogenesis of leukaemia in childhood is obscure. Several of the cases in the series presented many features of an acute infection, such as the sudden onset, often with fever, and the rapid course of the illness. The author suggests that the disease is not necessarily the same as in the adult, and that the various types he has described are possibly not all due to the same cause.

**424. Treatment of Infantile Paralysis by X-Rays and Diathermy.**

INSPIRED by the work of Bardier, A. G. LANOVSKY and G. M. FREYDOWITZ (*Meditsinskaya Mysl Uzbekistana* [Russian], October, 1927, p. 37) report the treatment by x-rays and diathermy of 39 cases of infantile paralysis during the first six months of the disease. A complete cure was achieved in 21 per cent., excellent results were obtained in 50 per cent., and in the remainder, with the exception of two cases of diffuse poliomyelitis, the therapeutic results were good. The treatment began with irradiation of the spine. When the lower limbs were affected, the rays were directed to the ninth, tenth, eleventh, and twelfth dorsal vertebrae; in paralysis affecting the upper limbs the fifth, sixth, and seventh cervical and the first dorsal vertebrae were irradiated. In cases of combined paralysis, both the upper and lower segments of the spine were treated. Each field was irradiated with 30 to 50 per cent. of the skin erythema dose with a filter of 0.3 mm. zinc and 1 mm. aluminium. The treatment was repeated at intervals of two to three weeks, and twice or three times altogether. Diathermy was employed every second or third day in the intervals between the x-ray treatments. A small electrode was applied to the affected segment of the spine, a large indifferent electrode opposite in front, and a current of 500 to 1,000 milliamperes was passed for ten to fifteen minutes. The course of treatment usually lasted from one to two months.

## 425. Sequels of Meningeal Haemorrhage at Birth.

M. RIVIÈRE (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, November, 1927, p. 643) reports the subsequent history of six infants, aged from 1 to 2 years, who at birth had had meningeal haemorrhage, which was proved by lumbar puncture. Four appeared to be normal, mentally and physically, and these included (1) a child delivered by forceps in a condition of asphyxia, whose apparently moribund condition, attended by ineffectual convulsions, improved *pari passu* with lumbar puncture repeated two or three times daily; (2) a child delivered by breech, in whom lumbar puncture was performed repeatedly, sanguineous fluid being replaced eventually by one which to the naked eye appeared purulent, but which was actually sterile. A fifth child had not walked at the age of 13 months and appeared to be lacking in facial expression; a sixth walked at 22 months. In a seventh case meningeal haemorrhage was diagnosed clinically, but not proved by puncture; this child was deficient mentally and parietic at 4 years of age, but there was a history of recent paternal syphilis.

## Obstetrics and Gynaecology.

## 426. Delivery of the Adherent Placenta.

J. JARCHO (*Surg., Gynecol. and Obstet.*, February, 1928, p. 265) reports three cases in which the Mojon-Gabaston method of removing the placenta was employed, with resulting delivery in from ten to forty minutes and uneventful recovery. By the injection of warm sterile saline solution into the umbilical cord vein the placental vessels become distended and ruptured, with the formation of a retroplacental hydroma; which mechanically causes separation of the placenta, thus avoiding intrauterine exploration with its attendant dangers. From 100 to 300 c.c.m. of warm sterile salt solution are injected slowly with a Record or Luer syringe into the vein of the umbilical cord, the navel being held in position by an artery clamp, which can be tightened to prevent any return flow of saline should a second puncture be found necessary. If required a rectal examination will determine whether the placenta after detachment is remaining in the cervix and vagina. Jarcho advocates the more general use of rectal examinations in obstetric practice as being easily and rapidly performed with a one-finger glove, and affording all the necessary information as to the progress of the labour. The bladder should always be emptied before injection, the site of which on the cord may be painted with iodine or mercurochrome. The method is useful also in febrile or infected patients; its performance is simple, requires no anaesthetic, and the injection being made into the unsolled portion of the protruding cord close to the external genitals, there is no danger of carrying infection.

## 427. The Heart in Pregnancy.

S. A. GAMMELTOFT (*Surg., Gynecol. and Obstet.*, March, 1928, p. 382) records the results of studies undertaken to ascertain the condition of the heart in pregnancy. Regular examinations throughout the pregnancy, and for a time afterwards were made. The examinations could not be completed in more than 239. Only those of normal physique between 20 and 35 years of age, and either primiparae or 2-parae, were selected, and during the whole period from the second or third month onwards they were examined every two or three weeks by the usual methods of auscultation, pulse, and blood pressure readings before and after exercise, record of weight, and x-ray and electro-cardiographic examination. In a smaller series the amount of blood circulating through the heart in one minute (the minute volume of the heart) was determined by the method of Krogh and Lindhard. While the majority of patients went through pregnancy and confinement without any unusual circulatory symptoms, 39 of the 239 perfectly healthy women presented during the latter half of gestation symptoms which during the last two months were so pronounced as to suggest an organic heart lesion, their chief complaint being cardiac pain, headache, and dyspnoea accompanied by rapid pulse, extra-systole, venous pulsation, and systolic and diastolic murmurs over the pulmonary and tricuspid valves. During labour there was no aggravation of the symptoms, and the murmurs disappeared as early as the next day; all symptoms had subsided before discharge. From these investigations and those of earlier observers the author concludes that apparently healthy women may develop functional symptoms during pregnancy which have often been considered as indicative of organic heart disease. Though his investigations do not conclusively prove cardiac hypertrophy, the heart's action is increased as a result of the larger total amount of blood and the increased amount circulating through the heart in one minute, thus explaining the development of hypertrophy and possibly dilatation.

## 428.

## Caesarean Section.

G. DECOURCY (*Amer. Journ. Surg.*, January, 1928, p. 30) reviews some recent modifications in the technique of Caesarean section, and describes his own operation devised to avoid that contamination of the peritoneal cavity and uterine incision which occurs when the amnion is ruptured within the uterus. To this end the entire gestation sac is delivered intact and is opened away from the field of operation. After delivery of the uterus through a rectus incision slightly to the left of the median line the intestines and abdominal cavity are walled off with saline gauze and the uterus is opened by a low incision commencing at the bladder and extending sufficiently high for easy delivery but not longer than is necessary, the resulting scar from such low incision being more secure. The entire gestation sac is then carefully stripped from the uterine wall and delivered *en masse*, an assistant removing it from the vicinity of the wound and rupturing the membranes, extracting the child, and tying and severing the cord. So long as the placental circulation is maintained there is no danger to the child; the separation from the uterine wall occupies about a minute. In eight consecutive deliveries without mortality to mother or child no difficulty has arisen in its performance. The author states that finding the placenta beneath the uterine incision need not occasion concern, and there is less danger of rupturing the sac if the separation starts with the placenta. By this method the risk of infection is reduced to a minimum, and the author contends that on account of its greater safety to the mother and child it should, in the majority of instances, be given preference to the use of high forceps, since by its use lacerations of the birth canal and the dangers of compression of the infant's skull are avoided.

## 429.

## Genital Neuralgia.

P. DALCHÉ (*La Gynécologie*, January, 1928, p. 5) discusses "habit" neuralgias of the female genital organs, and records cases in which the pain was of great intensity and was accompanied by a persistent burning sensation which did not yield to any treatment. This kind of pain was always intensified by the slightest touch, and by any voluntary movement such as walking. After a long period of misery the patients became anxious and irritable from loss of sleep and appetite. The author compares this type of pain with that occasionally noticed after trauma of nerves; particularly the median and sciatic. This similarity has led some observers to attribute the neuralgia to a sympathetic syndrome following a lesion of the periaxillary plexuses. Whatever the cause, there is no doubt that no organic lesion could be found even after the most minute examination. The patients were not hysterical or psychasthenic. The theory that a particular nerve may develop a habit of registering pain is considered by the author. He argues that, presumably, some initial cause starts the pain and the nerve continues habitually to record pain even after the cause has ceased to operate. Dalché suggests that this may be possible without any accompanying mental derangement. He remarks that such patients often explain their ills badly, and the present means of investigation are too incomplete to allow an accurate diagnosis to be made. Further investigation of the cause of the pain is required. Treatment tried includes psychotherapy, drugs, thermal waters, light, diathermy, ionization, and surgical treatment. In one woman relief was obtained by section of the internal pudendal nerve.

## 430. Influence of Thyroid Disease on Menstruation.

H. GARDINER-HILL and J. F. SMITH (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter, 1927, p. 701) discuss the type of menstruation occurring in cases of thyroid disease based upon 300 cases, including 9 cretins, 100 instances of adolescent goitre with varying degrees of disturbed function, 96 cases of exophthalmic goitre and hyperthyroidism, 41 of myxoedema, 24 of parenchymatous goitre, and 22 of thyroid adenoma, the basal metabolism being estimated to confirm the degree of thyroid activity. It is shown that, while such conditions do not always affect menstruation, any alteration tends to be in a uniform direction, the type of menstruation varying inversely with the degree of thyroid activity; thus hypothyroidism may be associated with excessive haemorrhage, and hyperthyroidism with amenorrhoea. In cretins menstruation was usually found to be delayed or absent unless the patients were adequately treated, when normal regularity was obtained. In adolescent goitre without other signs of thyroid disturbance menstruation was generally normal, but in the presence of hyperthyroidism the periods were apt to be delayed and scanty, or excessive if hypothyroidism existed. In exophthalmic goitre there may be no menstrual disturbance, but in severe cases the periods tend to become scanty or absent. When myxoedema occurs before the menopause menorrhagia is generally present, but since this condition frequently does not develop till after the menopause the impression has arisen that it is sometimes accompanied by

amenorrhoea. Parenchymatous goitre and simple adenoma are usually unaccompanied by any menstrual disturbance, unless, as was found in a small proportion of the patients, hypothyroidism is present, when menorrhagia may occur.

#### 431. Mucous-celled Carcinoma of the Cervix.

ACCORDING to M. REEB (*Gynecol. et Obstét.*, January, 1922, p. 1), whereas carcinomatous growths of the luteal mucosa not infrequently contain mucous cells, it is extremely rare to meet such cells in malignant tumours of the lining of the cervix uteri; nevertheless in both situations cells having a physiological mucigenous function are present. Mucous-celled carcinoma of the cervix has been recorded in eight cases only, to which Reeb adds a ninth. A 2-para, aged 36, sought treatment for debility, loss of weight, and a sticky colourless vaginal discharge; she added that recently slight bleeding had occurred after coitus. There was a softened and moist vagina; the anterior lip of the cervix was enlarged to the size of a hen's egg, with a soft, smooth, and very sticky surface which was not ulcerated, but bled after being touched. This lip after excision showed a cylindrical-celled adenocarcinoma which, near the internal os, had typical microscopical characters, but in the middle, and especially in the lowest third, there was extensive mucous transformation. Large quantities of mucin were present, distending and finally bursting the intraglandular cavities and infiltrating the stroma in large collections to which degenerated remnants of gland cells were attached. In contrast with the corresponding neoplasms in the rectum there appears to be no evidence that mucous-celled cervical carcinomas are specially malignant.

## Pathology.

#### 432. Haematology of Measles.

F. REDLICH and Z. MATERNOWSKA (*Monatssch. f. Kinderheilk.*, January-February, 1922, p. 178), during an outbreak of measles at Lemberg, examined the blood of twenty-two cases and came to the following conclusions. During the incubation period there is often a rise in the number of leucocytes accompanied by an increase of the eosinophils; in the prodromal stage the number of white cells falls, and there is at the same time an increase in the monocytes. During the eruptive period the diminution in the number of leucocytes persists and the percentage of the monocytes falls to normal. At the beginning of convalescence the leucocytes are normal in number or slightly increased, and there is a rise in the number of the eosinophils, plasma cells, and monocytes. There are also not infrequently cases in which the blood picture differs from the type described owing to such factors as constitutional peculiarities, age, recent diseases, intestinal parasites, and, last but not least, the character of the particular epidemic. The authors conclude that examination of the blood in measles may be of value, but that in doubtful cases the diagnosis must be guided mainly by clinical considerations.

#### 433. Hypersensitiveness to Tuberculin.

A. MOELLER, studying the phenomena of hypersensitiveness to various tuberculins, has come to the conclusion (*Med. Welt.*, February 25th, 1922, p. 281) that some of the interpretations of this reaction are untenable. He compares the hypersensitive reaction with the rashes of the exanthemata, and believes that a period of hypersensitiveness of variable duration appears at some time in all tuberculous infections; this is attributed to by-products of the contest between the organism and the invading bacilli, varying with the age and constitution of individuals; it is not due to antigens, and should not be regarded as a measure of immunity. These by-products may at times be present in minimal quantities only, and, since in young guinea-pigs giving a negative tuberculin reaction tuberculous lesions may often be found when the animals are killed and dissected, he considers the assumption unjustifiable that young infants who give a negative tuberculin reaction are free from tuberculous infection. He has also found that on the thin arm of an undernourished child a negative reaction may be obtained, although when the child becomes fatter again the reaction becomes positive. He adds that it has also been demonstrated in cattle that cutaneous hypersensitiveness may disappear for a time, and yet the animals may be very resistant to infection.

#### 434. Vitamin Deficiency and Liability to Infection.

C. E. BLOCH (*Ugeskrift for Læger*, February 23rd, 1922, p. 185) notes that while he and various other observers have found vitamin A deficiency give rise to defective immunity, as demonstrated by the existence of various infections

processes, no clinical or experimental investigations have hitherto been made with regard to the possibility of vitamin C deficiency having the same effect. He asks if vitamin C deficiency provokes the same degree of defective immunity as does vitamin A deficiency, and whether patients suffering from scurvy are appreciably more susceptible to infections, benign and otherwise, than other patients. To answer these questions he grouped his clinical material into two classes. In the first there were 32 cases of scurvy (vitamin C deficiency), and in the second there were 86 cases of xerophthalmia (vitamin A deficiency). Among the cases of scurvy there were 18 infants whose ages were between 6 and 12 months, and 14 children whose ages were over 1 year. Among the cases of xerophthalmia there were 20 infants under the age of 6 months, 27 between the ages of 6 and 12 months, and 39 children whose ages were over 1 year. Among the cases of scurvy there were 9 showing evidence of some infection on admission or during residence in hospital, but with the exception of one case of pneumonia and one case of pyuria and congenital syphilis complicated by vitamin A deficiency, these infections were of a slight catarrhal character and rapidly cleared up. The incidence and severity of the infections in this class were not greater than in other hospital patients whose principal ailment was not an infectious disease. On the other hand, among the 86 patients suffering from xerophthalmia there were 68 also suffering from some infection, which in 15 cases consisted of pneumonia, in 12 of bronchitis, in 13 of otitis media, in 27 of pyuria, and in 14 of purulent conditions of the skin. These severe infections did not disappear till the vitamin A deficiency had been overcome. The author concludes from these observations that, in Denmark at any rate, it is only vitamin A deficiency, among all the various vitamin deficiencies, which causes a marked fall in the state of immunity. He notes in this connexion that while in chronic tuberculosis the increasing of the supply of vitamin A is most beneficial, the increasing of vitamin C has little effect except in the rare cases in which the tuberculosis is complicated by scurvy.

#### 435. Chronic Suppurative Otitis Media Associated with Vincent's Organisms.

R. MOTTA (*Il Policlinico*, Sez. Prat., January 23rd, 1922, p. 83) describes the cases of two children with discharging ears; the slight discharge tended to be fetid, and the children were often noticed to rub their ears with their fingers. At a later date the discharge increased in volume and in fetor; it was found to contain large numbers of fusiform bacilli and the spirilla of Vincent. The first case was a chronic condition of nearly two years' standing; the second was of much shorter duration. In both cases there was painful enlargement of the upper deep cervical glands, and in the first case there was an ulcer in the external auditory meatus, about half a centimetre across. Both cases had been treated with hydrogen peroxide drops, but neither had improved. A solution of 10 per cent. salicylic acid in alcohol was tried but without success. Finally a 15 per cent. solution of neosalvarsan was applied locally and a very considerable degree of improvement was obtained. It was found that the spirilla of Vincent and fusiform bacilli gradually disappeared from the discharge, and many pseudo-diphtheria bacilli remained. The author thinks that the infection with Vincent's organisms may have been added by the fingers of the children.

#### 436. Acclimatization to Low Oxygen Pressures.

J. A. CAMPBELL (*Journ. of Physiol.*, September 9th, 1927, p. 325), continuing his investigation of acclimatization to low oxygen pressure equivalent to that of the top of Mount Everest, confirms the general rule that the haemoglobin percentage decreases as the oxygen pressure in the air rises, and vice versa. The changes produced by altering the oxygen pressure pass off again after a few weeks' exposure to the normal. Changes in the haemoglobin percentage are, however, not essential to acclimatization to alterations in the oxygen pressure, and should be regarded only as possible consequences; they are of some assistance to the heart when they do occur. Campbell adds that, contrary to the prevailing views, acclimatization to lowered oxygen pressure in the air is not due to improvement in the tissue oxygen tension, but to the fact that the tissues accustom themselves to the lower figure. Rapid acclimatization is due to the ability of the vital organs—particularly the heart—to continue to function under a low oxygen tension. In all animals experimentally exposed to low pressures heart failure was the most constant phenomenon. Acclimatization to increased oxygen pressure in the air was similarly found to be due to the tissues accommodating themselves to it. Hypertrophy of the muscular coat of the branches of the pulmonary artery was observed to follow exposure to low oxygen pressures.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 437. Latent Scurvy.

THOUGH scurvy is considered of rare occurrence, H. ÖHNELL (*Acta Med. Scand.*, March 15th, 1928, p. 176) believes that it is not so infrequent in Sweden as is thought, and that the symptoms are often so mild as to lead to an erroneous diagnosis. He has had twenty-two such cases under his care, and Meniengracht has this year reported eight cases in Denmark. Of the twenty-two patients, six (aged 21 to 61) were males and sixteen (aged 21 to 53) were females; all the cases seemed to be due to a lack of vitamin C in the diet, which had been modified in consequence of the existence of intestinal disease. The predominant feature in most of these cases was a gingivitis, localized to the proximity of the teeth and accompanied by intensively swollen interdental papillae, though rarely by marked bleeding. Cutaneous haemorrhages, almost exclusively confined to the lower extremities, were noted in most cases; these were usually isolated, but in a few cases were confluent. Haemorrhages in other organs were rarely observed, haematuria occurring only in one and slight haemoptysis in two patients. Tests for occult melæna were always negative. In two cases there was marked oedema of the lower limbs. Rheumatic pains and slight anaemia were often present, and nervous disturbances were very frequent. Öhnell adds that the presence of gingivitis and cutaneous haemorrhages, combined with a history of vitamin C deficiency, are the chief factors in diagnosis, which may be aided by a radiological examination of the teeth for the typical scorbutic changes which are often seen. Prophylaxis, difficult in intestinal diseases, consists in supplementing the diet as soon as possible with fruit and vegetable juices rich in vitamin C, the juice of oranges, lemons, tomatoes, or carrots being given daily in teaspoonful doses. In treatment Öhnell gives these juices in larger doses—namely, the juice of one or several oranges or lemons or 50 to 200 grams of tomato or carrot juice daily; since the vitamin content varies considerably in the same kind of fruit or vegetable, several different varieties are prescribed for each patient.

### 438. Venous Drainage of the Cardiac Nodes.

E. GÉRAUDEL (*Arch. des Mal. du Cœur*, March, 1928, p. 148) has established the fact that the cardiac rhythm depends upon the arterial supply of the nodes, and he now gives an account of the venous drainage of these structures. The bundle of His and the auriculo-ventricular node are drained by a vessel which closely follows the artery supplying them. This vein is joined by one flowing from the interventricular septum, and the main trunk then opens into the right auricle immediately above the valve of Thebesius. No vein is found corresponding to the principal artery of the sino-auricular node, but many small veins are present in this region, and they open into the posterior portion of the right auricle on the medial aspect of the crista terminalis. The author has previously shown that arterial ischaemia results in impaired cardiac action corresponding to the nodes involved, and he considers that comparable alterations of rhythm may follow passive hyperaemia of the nodes due to faulty drainage. Thus, since arterial hyperaemia augments the action of the heart, so hyperaemia of venous origin should exert the same influence. Support for this hypothesis is found in clinical medicine, for it is particularly in those cases of mitral disease associated with right-sided dilatation that tachycardia is most common. Passive hyperaemia of the nodes may, therefore, be the link connecting auricular distension with rapid cardiac rhythm.

### 439. Diphtheria of the Larynx in the Adult.

C. ZOELLER (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, March 8th, 1928, p. 426), who records a personal case, illustrates the rarity of diphtheria of the larynx in the adult by the fact that Collet had seen only eight examples. Megias reported three cases, none of which was recognized at the onset, while one was mistaken for tuberculous laryngitis. It is noteworthy that Bretonneau made a retrospective diagnosis of diphtherial laryngitis in the case of George Washington, who died at the age of 67. Zoeller's case was that of a colonel, aged 60, who had an attack of purely laryngeal diphtheria followed by paralysis of the palato and constrictors of the pharynx, but ultimately recovered. It was remarkable that, living as he did in a community where diphtheria was ubiquitous, he had not become immunized.

### 440. Meningococcus Septicaemia.

O. HERMANN and M. EIFSCHITZ (*Deut. med. Woch.*, March 2nd, 1928, p. 355) state that meningococcus septicaemia is not an infrequent occurrence. In all cases of suspected malaria, influenza, or enteric fever in which the diagnosis is not definitely established a repeated bacteriological examination of the blood should be made. According to Friedemann and Deicher, the characteristic features of meningococcus septicaemia are (1) catarrh of the nasal mucous membrane, throat, or bronchi; (2) fever, at first remittent and then irregular, from one to several months' duration; (3) erythema exudativum or nodosum; (4) protracted course without physical signs; (5) a relatively good general condition. The authors record a case in a man, aged 30, who presented all these symptoms and showed a pure culture of meningococci in the blood. Spontaneous recovery followed, the disease being apparently not affected by quinine, arsenic, or iron.

### 441. Transverse Myelitis as a Form of Heine-Medin's Disease.

C. HÜNNERMANN (*Arch. f. Kinderheilk.*, March 23rd, 1928, p. 251) records the case of a previously healthy boy, aged 14, in whom, during an epidemic of poliomyelitis, there developed paralysis of both lower limbs and retention of urine. There had been no trauma to cause haematomyelia, which might have given rise to these symptoms. Syphilis, tuberculous spondylitis, or a tumour which could have produced a transverse lesion could be excluded, as well as lead or arsenical poisoning. The diagnosis was therefore made of acute poliomyelitis in the form of transverse myelitis, of which several examples have been recorded in recent years, so that the description of a transverse myelitis form of Heine-Medin's disease appears justifiable. Since no normal horse serum or convalescent serum was available, antimeningococcal serum was injected intraspinally and intramuscularly, and in the course of three months recovery ensued.

### 442. Encephalitis following Measles.

P. H. KRAMER (*Nederl. Tijdschr. v. Geneesk.*, February 25th, 1928, p. 937), who records five illustrative cases, regards it as probable that encephalitis following measles is not due directly to the virus of measles, but results from the invasion of a neurotropic virus which is already present in the patient or has attacked him after the onset of measles. Kramer draws attention to the greater frequency of the occurrence of encephalitis in connexion with other infectious diseases in recent years in various countries, such as vaccinia, varicella, scarlet fever, and whooping-cough, and suggests that it may be connected with epidemic or sporadic cases of encephalitis lethargica.

## Surgery.

### 443. Prognosis in Foreign Bodies in the Gastro-Intestinal Canal.

J. GRÜNSTEIN (*Zentralbl. f. Chir.*, March 10th, 1928, p. 585) states that the majority of elongated foreign bodies that enter the alimentary canal are passed naturally per anum. Some, however, are retained, either on account of their size or because they become impacted in the region of an anatomical or pathological narrowing of the canal. Perforation of the large intestine by foreign bodies is very rare, but Brünning reported a perforation of the transverse colon by a fish-bone, which was found in an omental abscess; the perforation in the intestinal wall had healed completely. The inflammatory omental swelling was removed successfully. Grünstein now reports two other cases. A woman, aged 38, observed a hard mass in the left side of her abdominal wall below the umbilicus. She had occasional severe pain in this region, and her general health was failing. At the operation a hard, tender omental tumour, as large as the fist, was found firmly attached to the peritoneal surface of the abdominal wall. The adherent transverse colon was definitely thickened over an area two inches in diameter. With the probability of this being a carcinoma with omental metastases, the bowel was resected and an end-to-end anastomosis performed. The omental tumour contained a fish-bone and several abscesses. In the resected portion of the bowel there was a perforation which easily admitted a sound. The patient did well until the fourth day, when a sudden fatal haematemesis occurred. A man, aged 36, was said to have had recently a severe

attack of typhus with melaena. A skiagram showed a deep shadow, three fingers in breadth, below the liver margin, and a diagnosis of metallic foreign bodies was made. On opening the abdomen, a hollow viscus presented, densely adherent to the parietal peritoneum over an area as large as a five-shilling piece. This proved to be the stomach, and immediately beneath the pylorus a protrusion as large as a small apple was found. On opening this sac two coins and fifty-six straight and bent nails, some as long as 5 inches, were found. The patient made a rapid recovery. The author adds that reports of such cases, followed by successful operation, are very frequent, and prognosis is favourable if operation is not delayed.

#### 444. Myositis Ossificans.

T. R. CHAMBERS (*Arch. of Surg.*, March, 1928, p. 755) reports an unusual case of myositis ossificans occurring in a man, aged 28, who, while helping to lift a motor car, felt a sudden sharp pain in the upper part of his right arm and shoulder, which was followed by swelling and slight pain and tenderness. A month later an x-ray examination showed a definite bone-forming tumour of the outer side of the right humerus, which was thought to be due to the stripping of the periosteum at the insertion of the deltoid, the result of the indirect violence a month previously. Six months later the bony mass was larger and appeared to be extending round the shaft as a pedunculated bony tumour attached to the humerus at one point. It was at first thought advisable to defer operation until the mass had ceased growing, but a sudden rapid increase in size led to a decision to operate, and twenty months after the injury the mass was curetted down to the shaft and a considerable amount of periosteum with some cortex was curetted and chiselled off. The wound healed without any complication and the patient was freed from pain. Two months later recurrence took place, and steadily increased, threatening the blood and nerve supply to the arm. Amputation at the shoulder-joint was performed, and one and a half years later there was no evidence of any further involvement. Sections showed typical myositis ossificans without any sign of malignancy. Chambers comments on the possibility that the condition was due to indirect violence by muscular exertion, recurrence following removal before a stationary or receding stage had arrived. Had it not been that the earlier x rays showed the cortex to be intact without erosion or irregularity, a diagnosis of periosteal sarcoma would undoubtedly have been made after the first operation in view of the recurrence, and because the films then more closely resembled sarcoma, the mass being more irregular, and the cortex being irregular and eroded as the result of curetting.

#### 445. Treatment of Prostatic Hypertrophy.

G. H. EWELL (*Amer. Journ. Surg.*, February, 1928, p. 201) states that the mortality after operations on the prostate during recent years has fallen to about 3 per cent. as the result of careful pre-operative and post-operative preparation and treatment. The institution of bladder drainage and the forcing of fluids before operation is important. Acridavine is usually administered together with urotropine, and if cystitis is present bladder-irrigation is performed twice daily. The suprapubic operation gives excellent results, and the mortality is low with this method. Nitrous oxide or ethylene gas are the anaesthetics of choice. Complete haemostasis after operation is the second most important factor in the management of these cases; this is secured by gentleness and care in the coagulation, and by the use of some mechanical pressure. The Pileher bag is useful, but the gauze pack is to be preferred. This is soaked in glycerin and packed tightly into the gland cavity. Bladder irrigation is started about the fourth day. Epididymitis is a frequent complication and may retard convalescence. Double ligature and division of the vas prevents this and should be performed.

#### 446. Death in Acute Intestinal Obstruction.

W. D. GATCH, H. M. TRUSLER, and K. D. AYRES (*Surg., Gynecol. and Obstet.*, March, 1928, p. 332), discussing the cause of death in acute intestinal obstruction, conclude that in simple obstruction without gangrene death is not due to absorption of toxins, but results from dehydration and the loss of chlorides through vomiting and starvation; in acute strangulation, however, death is due primarily to toxin absorption from bacterial action in the distended and gangrenous bowel, which quite overshadows the dehydration and hypochloraemia. In simple pyloric or duodenal obstruction operation should be postponed until the dehydration, hypochloraemia, and starvation have been overcome by the intravenous administration of sodium chloride, glucose, and water; in early stages of intestinal obstruction the operation should be performed as soon as the blood chlorides have reached

a normal level. The authors think that, unless the patient is moribund, the prognosis of acute simple obstruction should be favourable, provided that the metabolic disturbances resulting from dehydration and loss of chlorides can be relieved by the administration of sodium chloride solution. In obstruction complicated by gangrene, such treatment, while it supplies fluids and chlorides and increases kidney elimination, does not relieve the toxæmia, which is closely allied to that of surgical shock; such patients stand anaesthesia badly, and the operation should always be preceded by the intravenous administration of a considerable quantity of sodium chloride solution. The gangrenous loop should be excised and enterostomy performed, an intestinal anastomosis being postponed until the patient has recovered, and not being undertaken in the presence of great distension of the bowel.

## Therapeutics.

#### 447. Heliotherapy and Renal Tuberculosis.

A. ROLLIER (*Brit. Journ. of Tuberculosis*, January, 1928, p. 9) outlines the important position which heliotherapy occupies in the treatment of renal tuberculosis as a most valuable subsidiary agent. He considers nephrectomy essential as soon as the diagnosis of unilateral renal tuberculosis is established because of the risk of bladder infection. In such cases heliotherapy is of use, and is especially indicated in the pre-operative stage for those patients whose general condition is precarious and who are likely to be poor operative risks or to suffer from post-operative complications. It is claimed that heliotherapy induces repair of tuberculous lesions, improves the circulation, increases the general powers of resistance, and, by developing local cellular resistance in the area of the operation, it lessens the risk of wound infection. Post-operatively heliotherapy gives excellent results by assisting healing, destroying germs, and stimulating the cellular defence. In bilateral disease it is the treatment of choice in helping the organism to fight against extension of the tuberculous lesions and exerting an analgesic action upon ulcerations of the bladder. To be efficacious its administration demands strict adherence to proper dosage for each individual case, so that the local and general reactions never become so intense as to be dangerous. Application to the whole surface of the skin, commencing with the lower extremities, is of importance, the different regions of the body being exposed in short sessions at intervals of five minutes, repeated three times. Local treatment should rarely exceed thirty minutes for the kidney or bladder. Rollier advises patients to take up some form of work which, combined with the sun cure, exercises a valuable psychotherapeutic influence.

#### 448. Arsenic and Bismuth Therapy in Hodgkin's Disease.

ALTHOUGH certain chemical preparations exercise a rapid and radical effect at first on the glands in Hodgkin's disease MICHAELIS (*Bruxelles-Médical*, March 18th, 1928, p. 677) gives the warning that the prognosis should be guarded, since in the final stages their action is inefficacious. He reports an illustrative case of a woman, aged 52, who when first seen had an enlarged gland behind the right ear. Treatment with an iodine ointment and hot moist dressings caused no improvement, and, three weeks later, further enlarged indurated ganglia were found in the neck and arms. Cytological examination of the blood revealed no special features; the Wassermann reaction was negative, and the family history was inconclusive as regards syphilis. At this time the right parotid gland commenced to enlarge, and a diagnosis of epidemic parotitis was tentatively made. Three intramuscular injections of eparseno (12 cg.) were given, which were followed by decrease in the parotid and in the subcutaneous and submaxillary glands, though other enlarged glands appeared. Two further injections of eparseno were not well tolerated, and three injections of mercury cyanide were given. The parotitis completely subsided, but an attack of general pruritus supervened. Owing to the persistence of the adenitis, which proved that the parotitis was secondary and not primary, and the continued negative character of the blood reaction, a diagnosis of Hodgkin's disease was now made. Fearing the action of arsenic on the liver Michaelis now employed injections of Millot's benzo-bismuth (20 cg.) twice weekly. This at first had a rapid action on the ganglia, but later another ganglion appeared in the right axilla, and the right breast became enlarged and congested. X rays were tried, but without effect. The patient became emaciated; cough, dullness over the intercostal and posterior region of the right lung, and enlargement of the liver occurred. The blood still showed no changes, and now a diagnosis of lymphosarcoma terminating the Hodgkin's disease was made. At the end of the seventh month the patient died, pneumonia

not supervening, since the pulmonary tumour did not undergo necrosis or suppuration. Michaelis draws attention to the initial beneficial action of the arsenic and bismuth in this case, and suggests that this was possibly due to the presence of a syphilitic terrain upon which the Hodgkin's disease developed.

#### 449. Thallium Acetate in Ringworm.

B. F. FELDEN (*Arch. Derm. and Syph.*, February, 1928, p. 182) records his experience of treating forty-seven children with ringworm of the scalp by oral administrations of thallium acetate; of these, thirty-six were cured by one dose. The dose was 8 mg. of the drug for each kilogram of body weight; it was dissolved in half a glass of water sweetened with sugar, and given on an empty stomach in the morning. Eplilation usually occurred on the eighteenth day, but was only entirely complete in approximately 50 per cent. of the cases, the remaining loose hairs being painlessly extracted by strips of adhesive plaster; in some cases only partially successful results were obtained. In from three to four weeks the hair began to grow again and during the whole period daily local treatment with 5 per cent. tincture of iodine and 10 per cent. sulphur ointment was continued; it was found that this did not cause irritation, thus constituting an advantage as compared with x-ray treatment. Patients with a marked discrepancy between weight and age are said to be unsuitable for pure thallium treatment, but a modification consisting of one-half or two-thirds of the doses of both x-rays and thallium combined gives good results. On account of its toxicity full dosage must be avoided in adults and adolescents; repetition of the dose in less than two months is dangerous, and acute infections and kidney diseases are contraindications for its use. Symptoms of poisoning are: muscle and joint pains, choreiform convulsions, albuminuria, gastro-intestinal disturbances, achlorhydria, secondary anaemia, and tachycardia. Felden regards the drug as of value in producing eplilation in children, but warns against its indiscriminate use by those who are not familiar with its grave toxic qualities and contraindications.

## Anaesthetics.

#### 450. Ocular Complications of Spinal Anaesthesia.

J. ROLLET (*Journ. de Méd. de Lyon*, March 20th, 1928, p. 167) states that ocular complications following spinal anaesthesia, which were first described by C. Adam and then by Doesser and Roeder in 1906, are rare, their frequency being about 1 in every 300 cases of spinal anaesthesia. Paralysis of the external rectus are far the commonest, occurring in more than 90 per cent. of the cases. Involvement of the oculomotor nerve is much rarer. Paralysis of the external rectus is generally unilateral. Other ocular palsies are exceptional. In spite of the toxicity of cocaine, most of the paralyzes have followed the use of stovaine or novocain, and in only one or two cases has cocaine been incriminated. As regards the size of the dose, although at first paralyzes occurred even after small doses, at present they have mainly followed large doses. The ocular paralyzes may be sometimes accompanied by affection of other cranial nerves, while signs of a meningeal reaction are constant. The paralyzes usually appear a week after the operation, and subside in the course of six or seven weeks. Of the numerous theories suggested to explain their occurrence, the most likely appears to be localization of an attenuated meningeal process following spinal anaesthesia. It is possible that a previous taint, such as syphilis, may cause a special disposition. Recovery is usually spontaneous, but may be hastened by treatment with strychnine or urotropine combined with antisyphilitic drugs.

#### 451. Splanchnic Anaesthesia in Upper Abdominal Operations.

H. E. MURRAY (*Indian Med. Gaz.*, March, 1928, p. 117) mentions the difficulties and annoyances encountered in surgery of the upper abdomen which can be obviated by anaesthesia of the splanchnic area; he has adopted this method in twelve cases with striking results. Within two or three minutes of induction the patient is breathing without distress; there is no protrusion of the intestines into the operation area or out of the abdomen, and the amount of general anaesthetic required is considerably lessened. Two strengths of novocain, 1/2 and 1 per cent., and a 50 c.cm. and 30 c.cm. syringe are employed, 100 c.cm. of the 1/2 per cent. solution being used for the first step and 30 c.cm. of the 1 per cent. for the second. General anaesthesia having been started in the usual manner, the needle is inserted into the skin and deeper tissues at the lowest point of one of the costal arches. When the rib or cartilage is felt the needle point is depressed, passed for

a short distance under the arch, and some of the 1/2 per cent. solution is injected into the tissues surrounding the intercostal nerve. The needle is then withdrawn, inserted a little higher up, and more solution is injected. This is repeated until the ensiform cartilage is reached, and the opposite costal arch is similarly treated. After opening the abdomen the lesser gastric curvature is defined and the fingers of the left hand are introduced above it until the body of the first lumbar vertebra is felt just above and to the right of the origin of the coeliac axis. The index and middle fingers are then slightly separated, thus pushing the aorta to the left and leaving an area devoid of blood vessels on the vertebral body. The needle is passed into this space and on to the body of the vertebra; the 1 per cent. solution is then slowly injected. Care must be taken not to puncture a blood vessel, but, if this should happen, the needle must be withdrawn and inserted in another place. No adverse sequelae have been noted in any of the cases.

#### 452. Regional Anaesthesia for Operations upon the Spinal Column.

G. LABAT (*Anaesthesia and Analgesia*, January-February, 1928, p. 38) points out that the principles involved in the induction of regional anaesthesia for orthopaedic operations upon the spinal column differ to some extent from those underlying the technique for other operations, since they have usually to be made in regions where the landmarks have been distorted by trauma or disease, and that therefore the anaesthetist must have a thorough anatomical knowledge. The best posture for the patient is lying prone; this facilitates the paravertebral injection technique and keeps the back muscles as relaxed as possible. Induction of paravertebral block by approaching the nerves from a point overlying the transverse processes is advised, since the same wheels are used for the field-block. By producing the "barrage" as near the middle as possible forcible retraction does not cause any discomfort; part of the injection finds its way through the wound, and the resulting ischaemia of the operative field facilitates dissection. A 0.5 per cent. solution of novocain with the addition of five drops of adrenaline solution (1 in 1,000) to each 100 c.cm. injected is advised to delay absorption and increase the duration of the anaesthesia. Not more than 250 c.cm. should be very slowly injected, it being borne in mind that perfect anaesthesia should not be sacrificed to the possibility of slight circulatory reactions which have no clinical significance. Under regional anaesthesia decompression of the cord is rendered less difficult and hazardous; extensive spinal fusions can be performed with but little post-anaesthetic disturbance and greatly improved prognosis, especially in the presence of active pulmonary tuberculosis.

## Obstetrics and Gynaecology.

#### 453. Cystic Swellings of the Abdominal Wall Following Trauma.

W. KOLDE (*Zentralbl. f. Gynäk.*, March 3rd, 1928, p. 553) describes two cases to illustrate the diagnostic difficulties which may be caused by large subcutaneous collections of fluid in the abdominal wall. The first patient, a woman aged 46, reported abdominal swelling and general wasting of fifteen months' duration; the appearance of the abdomen (its girth was 4 ft. 5 in.) together with the emaciation suggested a giant ovarian cyst, but the indefiniteness of the limitation of the tumour above and below led to a diagnosis of ascites from intra-abdominal carcinoma (primary focus unknown) or of peritoneal tuberculosis. Incision of the skin as a preliminary to laparotomy gave issue to nearly nine gallons of greenish-brown fluid containing necrotic shreds, and the tumour was emptied without incision of the abdominal cavity; microscopical examination of the cyst wall pointed to its having a lymphatic origin. The patient's health and weight were subsequently fully restored. Questioning elicited the statement that the abdominal swelling had been preceded by a fall with direct violence to the abdomen. In the second case a fall into a pit at work was followed by the admission of the patient, a 1 para aged 22, to hospital; fracture of two ribs was noted, as well as morbid physical signs in both lungs, and a diagnosis of military tubercle was made. A collection of pus in the pouch of Douglas was evacuated by the posterior fornix, but an abdominal swelling, thought to be due to abdominal tuberculosis, did not regress. At operation a large abscess was evacuated from the space between the abdominal wall muscles and the peritoneum. The fall was thought to have caused the formation in this region of a haematoma which had become infected by the blood stream from the pelvic abscess. Kolde adds that to arrive at a correct pre-operative

diagnosis in cases of collections of fluid in the abdominal wall appears, from the cases recorded in the literature, to be exceptional; among the diagnoses made have been ileus, twisted ovarian tumour, cholelithiasis, and strangulated hernia. Treatment, except in the case of small haematoma, is surgical; if it is too long delayed there is danger of secondary infections and of grave cachexia.

#### 454. Chronic Endocervicitis.

C. J. MILLER (*Surg., Gynecol. and Obstet.*, March, 1928, p. 337), discussing the considerations that the treatment arise from manifestation of the cause. Since the cure to spontaneous cure, and gives rise to sequelae which may be very serious, prompt treatment is necessary; any surgical procedure should be preceded by a course of treatment with a view to reducing hypertrophy and inflammatory reaction and to restoring the normal relation of the parts. Local treatment has been found very unsatisfactory, and diathermy, ionization, alcoholic injections, and vaccines are only moderately effective, while radium is too dangerous for routine employment. In a large number of cases endocervicitis may be averted by prophylaxis, especially soon after parturition. Cauterization, trachelorrhaphy, or removal of the gland-bearing area of the cervix by the Sturmdorf operation may be needed, but amputation of the cervix should be avoided whenever possible. If there should be the slightest evidence of stenosis after the use of the cautery graduated dilatation must be promptly instituted. Miller agrees with the suggestion of Matthews that the indications for cauterization may be widened if it is performed unilaterally so that one lip is allowed to heal before the other is treated.

#### 455. Bladder Irritability of Rectal Origin.

H. EXNER (*Zentralbl. f. Gynäk.*, February 25th, 1928, p. 498) reports a case in which irritability of the bladder was kept up by an abnormal rectal condition after the original cause had been removed. The patient, a married nullipara, aged 40 years, had complained of frequency of micturition for five years. The urine showed no abnormality. Directly behind the bladder in the anterior wall of the uterus lay a fibroid as large as a fist and fixed in the pelvis. The vagina was double, with two external orifices, and the uterus was septate. After hysterectomy the bladder condition improved, but did not disappear, and the patient then stated that she had had anal tenesmus and painful and difficult defaecation since the beginning of the frequent micturition. On examination the external sphincter was found to be greatly hypertrophied, the mucous membrane was thrown into folds tightly pressed together with tiny faecal masses and rhagades between them, and the levatores ani were also very strongly developed. About a year after the hysterectomy the sphincter and levatores ani were thoroughly stretched and the bladder trouble ceased entirely. The condition was thought to be due to the strenuous efforts of the patient to control the frequent and precipitate micturition. She contracted the whole pelvic floor, causing it to hypertrophy; the unfolding of the mucous membrane, with faecal retention and formation of rhagades, led to the tenesmus of the external sphincter ani.

### Pathology.

#### 456. The Nature of Bacterial Anaphylaxis.

J. TOMCSIK and T. J. KUROCHKIN (*Journ. Exper. Med.*, March 1st, 1928, p. 379) remark that the main difficulty in studying bacterial anaphylaxis is the primary toxicity of the bacterial protein; Doerr showed that the amount of bacterial antigen which produces shock in sensitized animals is negligibly smaller than the lethal dose for normal animals. Zissner and Mallory reported that active sensitization is rendered very difficult because the bacteria contain a little coagulable protein, and that in animal tissues than in the case of protein antibodies. The present authors think, however, that the primary toxic substance of the bacteria is not necessarily identical with the specific antigenic part and that it might be possible to isolate an atoxic specific constituent responsible for anaphylactic shock. The discovery of specifically acting polysaccharides led them to investigate whether animals could be sensitized to carbohydrate haptines, either actively by the injection of bacteria, or passively by immune serum. Using guinea-pigs, experiments were made with *B. lactis aerogenes*, pneumobacilli, and a yeast. No reaction was noted in any of these tests in actively sensitized animals, but in the passively sensitized ones bacterial anaphylaxis was produced, *in vivo*

and *in vitro*, with haptines from each of the test micro-organisms. The smallest amount of haptine giving rise to fatal anaphylaxis was less than the minimal quantity of protein which caused death in properly sensitized animals. The haptines used were largely carbohydrates, but since they contained a small amount of nitrogen, it could not be positively asserted that carbohydrate alone will produce shock. Since haptines will not sensitize animals, these investigators conclude that the anaphylactogenic and shock-producing parts of the antigen are not identical, and that the experiments provided further evidence of the close relation between precipitins and anaphylaxis.

#### 457. Death from Air Embolism.

L. JUNG and L. AUGER (*C. R. Soc. de Biologie*, March 9th, 1928, p. 610) recall that many explanations have been given of death from air embolism—such as pulmonary embolism, nervous disturbances, and distension of the right ventricle leading to paralysis of the heart. Their own experiments suggest a different pathogenesis. To kill a dog it is necessary to inject at least 50 c.cm. of air into the right ventricle or at least 100 c.cm. into the jugular vein; moreover, this amount must be injected in the course of a few seconds. If the air is injected sufficiently slowly, an almost indefinite amount can be used. Immediately after injection there is a sudden fall of pressure in the carotid artery to 30 to 40 mm. of mercury. The right auricle and ventricle dilate rapidly, and a peculiar sound is heard during systole. After a short time numerous bubbles of gas are seen in the coronary veins passing in a retrograde direction till they reach the finest branches, where they stop. Shortly afterwards both ventricles enter into fibrillation, while the auricles continue to beat. At this moment the right heart, the great veins, and often veins at a considerable distance are filled with a foaming mass of blood. If the air is introduced into the left ventricle, only 20 c.cm. is required to cause death; almost immediately gas bubbles enter the coronary arteries, where they come to a standstill, and the two ventricles pass into fibrillation very rapidly. In neither instance were any appreciable lesions found in the lungs, nor did section of the medulla or vagus nerves alter the cardiac manifestations. In interpreting these findings the authors consider that ventricular distension is by itself insufficient to cause death, partly because it does not occur when the injection is made into the left heart, and partly because it cannot explain the simultaneous arrest of both ventricles. They believe rather that death occurs from embolism of the coronary arteries when the air is injected into the left ventricle, and from retrograde embolism of the coronary veins when it is injected into the right ventricle; in each case the coronary embolism is followed by ventricular fibrillation and death.

#### 458. The Relation between Glucose in the Blood and Spinal Fluid.

ACCORDING TO S. KATZENELBOGEN and Mile M. STOILOFF (*Ann. de Méd.*, February, 1928, p. 160) no significance can be attached to the amounts of glucose in the spinal fluid which some authors consider excessive, because such quantities have been noted both in different pathological conditions and in normal subjects; they conclude that the hypothesis that hyperglycorrhachia is due to a local trouble in the cerebro-spinal axis favouring the passage of glucose from the blood to the spinal fluid must be abandoned. The interdependence of the blood and cerebro-spinal glucose in diabetics has been long known, but in non-diabetics the figures vary greatly. Derrien estimates the spinal fluid glucose content as half that of the blood content, while Polonowsky and Dnhot think these amounts are equal, and other workers report figures between these extremes. In order to ascertain if a "haemo-meningeal" relation exists—a relation depending not only on the amount of glycæmia, but also on modifications of the cerebro-spinal axis—the authors examined forty-two cases of different maladies—namely, meningitis, nervous and mental troubles, and diseases of the respiratory, gastric, and circulatory systems, and one of meningitis and one of to be lower than the figure of Derrien, and in the other cases the ratios varied from 0.41 to 0.83. It has been shown that experimental aseptic inflammation of the meninges increases their permeability for nitrates, but that the amounts of these salts which pass into the spinal fluid are not proportional to the intensity of the inflammation. This variation in permeability is still greater for glucose. The authors believe that the amount of glycorrhachia is dependent in a certain measure on the degree of glycæmia, but more so on the meningeal permeability, which, favoured by meningeal congestion, is subject to important physiological variations. They maintain that an increased ratio between the blood and cerebro-spinal glucose has no semeiological significance.

### 

#### 

A. CLERC and R. LÉVY (*Bull. et Mém. Soc. Méd. Hôp. de Paris*, March 22nd, p. 490), in an investigation of heart-block, found that this condition might occur in children and young adults as well as in middle-aged patients, although Adams-Stokes attacks were less liable to complicate the juvenile group. They describe four cases in which heart-block was either constantly or usually complete in patients between 20 and 28 years of age. Such cases may be classified into those which are uncomplicated and those in which there is a coexisting congenital cardiac defect; cases in the latter group are usually diagnosed before the age of 10 on account of the accompanying cyanosis, while those without complications remain unrecognized until 20. Diphtheria is an important etiological factor, but rheumatism is not; the influence of syphilis and congenital heart disease is not known. The development of the condition is slow, and though syncope or convulsive attacks may supervene whether the block is complete or not, they occur only in one-third of all cases. Since congenital malformations are themselves of grave import, prognosis as regards life is better in the uncomplicated cases; these withstand intercurrent infections, operations, and even pregnancy very well, and frequently the patient suffers no ill effects from strenuous exercise, although there is a tendency for syncope attacks to follow violent exertion. Restoration of normal rhythm never occurs. For treatment, the authors advise salubrine in small doses, alternating with belladonna: sports should be forbidden and the avoidance of pregnancy is recommended in view of the danger of Adams-Stokes attacks.

#### 

C. T. OLCOTT and J. G. MERSHIS (*Amer. Journ. Dis. Child.*, February, 1928, p. 250) record a case of pulmonary gangrene following a severe attack of faucial diphtheria, which proved fatal on the twelfth day of disease. A diagnosis of pulmonary gangrene was made only forty-eight hours before death owing to the signs of pulmonary consolidation and the foul odour of the breath. There was practically no sputum. An x-ray examination showed irregular patchy consolidation scattered throughout both lungs, with areas of cavitation in the right lung. At the necropsy the lower two-thirds of the right lung were found to be completely gangrenous. Smears from the lung showed Vincent's organisms, and cultures yielded abundant diphtheria bacilli, non-haemolytic streptococci, and staphylococci. The authors believe that no similar case of pulmonary gangrene following diphtheria has been recorded.

#### 

M. OBERMAYER (*Derm. Woch.*, March 3rd, 1928, p. 297) remarks that until recently most authorities maintained that one attack of herpes zoster conferred a lifelong immunity, and only a few examples of second attacks of zoster have been recorded. Obermayer reports the case of a man, aged 32, who in the course of a few years had eleven recurrences of typical left lumbosacral zoster, accompanied by the characteristic constitutional disturbance in the prodromal stage, inguinal adenitis, and neuralgic pain. The patient had had an attack of varicella in childhood. In contrast with previously reported cases the latest attacks were more severe than the previous ones. Sexual excesses appeared to be causally connected with the eruption, which usually developed after an "incubation period" of two to four days. A somewhat similar case of recurrent zoster is reported by Richter in connexion with menstruation.

#### 

R. BÉNARD (*La Médecine*, December, 1927, p. 184) gives the following statistics of orchitis in mumps based on personal observations of 403 cases of mumps and study of the official statistics of the French army during the period 1892-1913 relating to 173,197 cases. The frequency of mumps in the French army varies considerably from one year to another, ranging from 9 to 33 per 1,000 of the total strength. Laveran estimated the incidence of orchitis at 33 per cent., Hudelo at 60 per cent., Catrin and Wesselhoef and Bénéard himself at 18 per cent. In former times, when soldiers were not admitted to hospital for mumps and were often kept on duty, orchitis was much more common than at present. Laveran collected 1,075 cases of mumps, complicated by orchitis in 184, of which

21, or almost 1 in 9, were bilateral. In Bénéard's series 1 in 15 of the cases of mumps orchitis was bilateral. As regards the frequency of testicular atrophy following mumps orchitis only two of Bénéard's patients had any atrophy, and this was very slight and unilateral on discharge from hospital; eight others showed a diminution in the size of the testis from one-third to one-quarter some months later. Bénéard considers cases of bilateral orchitis with atrophy, impotence, and feminism as mythical, both on statistical and anatomoclinical grounds.

#### 

J. A. ELLIOTT and L. C. TODD (*Arch. Derm. and Syph.*, March, 1928, p. 299) report a case of early syphilitic hepatitis in which the blood bilirubin determinations afforded an aid to diagnosis and a guide to treatment. They adopted the icterus index as a quantitative estimate of the bilirubin in the blood, using the van den Bergh test qualitatively to determine the type of jaundice: in the earlier stages of the case this latter test indicated that the jaundice was due to injury of the hepatic cells. The patient, a man, aged 25, suffering from severe jaundice, gave a strongly positive Wassermann reaction two months after the development of a sore on the penis. Because of the severity of the liver disturbance 0.1 gram of bismuth was injected at weekly intervals, and after the third injection improvement, both subjectively and objectively, was rapid, the index having become normal and the patient feeling well after having received twenty injections. In twenty-five control cases both tests were used to determine the effects of early syphilis and of treatment on the liver function, as shown by the bilirubin content of the blood. With three exceptions the blood was normal for bilirubin throughout treatment, with, in some cases, as many as twenty neocarsphenamine and from fifty to sixty bismuth injections. All the reactions in these three indicated only a slight increase of blood bilirubin content at one time during treatment. In the case of early syphilitic hepatitis recorded treatment with bismuth proved to be of great value.

#### 

M. KRABEL (*Zentralbl. f. Chir.*, March 31st, 1928, p. 781) refers to the difficulty in the differential diagnosis of acute appendicitis and cyclical vomiting in children. Although numerous articles on acute appendicitis in children have appeared in recent years scant attention has been paid to the symptoms of acetonæmia, although these often simulate those of acute appendicitis. Krabel records the case of a delicate boy, aged 6, who had had severe indefinite abdominal pain for thirty-six hours, accompanied by violent vomiting, which was becoming worse. Although there was no definite tenderness over McBurney's spot gangrenous appendicitis was suspected. There was profound collapse, dry tongue, and a small and rapid pulse, but the rectal temperature was normal. He was quite conscious, and complained of pain in the right side of the abdomen, but there was no muscular rigidity. A distinct odour of acetone was detected in the breath; sugar and a trace of albumin were found in the urine. During the examination the child vomited spasmodically and frequently. The operation revealed a completely normal appendix and peritoneum. Twelve hours later the child's condition was unchanged and the vomiting persisted with a distinct odour of acetone. The urine contained traces of acetone, diacetic acid, and sugar. Two 5-unit doses of insulin were given; the vomiting ceased and the child's condition improved rapidly. In two days the acetonuria disappeared and recovery was uninterrupted. Krabel states that cyclical (acetonæmic) vomiting is rare in that district (Aachen Forst). It is characterized by the sudden onset of intractable vomiting, with sudden collapse, acetonæmia, and possibly acetonuria. The etiology is obscure; constitutional diathesis may be a factor, as this patient's elder brother had a similar, though less serious, attack. The production of ketone bodies is not the cause of the vomiting, but is a concomitant symptom. Free administration of carbohydrates and of insulin is indicated, and the possibility of recurrence must be remembered. Krabel hopes that this report may prevent other surgeons from performing unnecessary appendicectomy in such cases.

**465. Ligature of the Inferior Vena Cava.**

M. PATEL and R. PEYCELON (*Lyon Chir.*, January-February, 1928, p. 22) report a case of ligature of the inferior vena cava after nephrectomy for a large tuberculous kidney. A woman, aged 37, complained of acute pain in the right lumbar region, pus in the urine, and a swelling in the right flank, which had increased in size during the previous three months. This swelling, which was painless and about the size of an adult head, was found at the operation to be a very hard and pedunculated tumour. Along the big vessels there were numerous large glands; the renal artery was normal, but the renal vein was much dilated and obscured by a fatty mass at the hilum of the kidney. This was freed and ligatured, and the tumour removed. A few seconds later a large jet of venous blood sprang from the bottom of the wound near the vertebral column, and obviously from a tear in the inferior vena cava, which was sutured by a catgut ligature above and below the rent. The tumour weighed 1,500 grams, and was composed of many pockets filled with caseous material and containing also many calculi. The patient suffered only slightly from shock, the urine soon became normal, and the temperature scarcely rose. There was a slight swelling in the legs at the end of eight days, but this only lasted for two days. The patient got up on the fifteenth day and has had no further trouble, there being no outward indication that the inferior vena cava had been ligatured.

**466. Disinfection of the Hands with Hydrogen Peroxide.**

R. FRANK (*Zentralbl. f. Chir.*, March 3rd, 1928, p. 514) has found that when hydrogen peroxide is mixed with soap a copious foamy lather is formed and the nascent oxygen penetrates deeply into the pores and fissures of the skin, destroying any bacteria without injury to the epidermis. Frank recommends the following procedure for sterilizing the hands before an operation. After thoroughly washing them with soap the hydrogen peroxide is allowed to fall in drops on the hands, which are constantly rubbed together, and the nails and subungual spaces are scrubbed thoroughly. This process is repeated three times and the foamy lather washed off in a stream of hot water for one minute. The hands are then rinsed with 30 to 40 c.cm. of the hydrogen peroxide solution and dried with a sterile swab; this is said to be most important, as the swab will remove any bacteria remaining on the skin surface. Frank finds that this renders the hands practically sterile, and that subsequent washing with alcohol does not materially increase the freedom from bacteria. A. LIPPAY (*ibid.*, p. 519) mentions that he has employed Frank's method with very good results in over 800 operations, and found hydrogen peroxide much more satisfactory than mercuric chloride solutions. Lippay uses an elevated irrigator with a tap adjusted to deliver 100 to 150 drops of hydrogen peroxide solution per minute. Among his 800 operations were 180 laparotomies, as well as thyroidectomies, and operations on bones and joints. He thinks that the primary healing without reaction obtained in all these cases is a proof of the practical value of hydrogen peroxide-soap sterilization.

## Therapeutics.

**467. Mercurial Diuretics in Ascites.**

L. BLUM and P. CARLIER (*Presse Méd.*, March 21st, 1928, p. 353) find that although mercurial diuretics are often of great value and that their toxicity is relatively low, they may fail to give relief and produce serious toxic symptoms, including pyrexia, rigors, stomatitis, and colitis. They report the case of a man, aged 56, who had hepatic cirrhosis with severe ascites, anasarca, and cholaemia. Transient relief followed the administration of large doses of calcium chloride, but the quantity of urine diminished, and the oedema increased when the calcium chloride was discontinued. An intramuscular injection of novasurol (0.22 gram) produced copious diuresis and a loss of 7½ lb. in weight; on the following day the patient became worse, and died eight days later from cholaemia. A further danger mentioned is that a single injection of one of these diuretics does not always suffice. The authors recommend the administration of large doses of calcium or ammonium chloride in solution with raspberry syrup to disguise the taste before or after the injection of the mercurial preparation. They describe a case of atrophic cirrhosis with severe ascites in which this treatment was successful. Injections of mercurial compounds were tried without permanent benefit and the patient was then given 150 grains of calcium chloride daily, for four days, followed by an intramuscular injection of neptal, a mercurial preparation. This produced marked diuresis (8 pints in twenty-four hours), with a loss of 6½ lb. in weight. Thus three mercurial diuretics failed, in the

absence of a preliminary course of calcium chloride. The authors describe a similar result in the case of a man aged 42, who had cardiac dilatation and hepatic cirrhosis. They add that ammonium chloride has certain advantages; it does not, like calcium chloride, cause constipation, and has a less unpleasant taste. They recommend that when an intramuscular injection of a mercurial diuretic has failed, one or other of these chlorides should be given for three or four days. In chronic nephritis with hypertension and abundant albumin, either calcium or ammonium chloride may be dangerous, by increasing the retention of chlorides. In such cases the authors consider that mercurial diuretics are contraindicated.

**468. Vitamin B Extract in Diabetes.**

As the result of four years' clinical experience of its action, C. A. MILLS (*Amer. Journ. Med. Sci.*, March, 1928, p. 376) believes that vitamin B stimulates the utilization of glucose in the body. He has found it very effective in increasing the appetite and rate of growth both in children and adults, and, since increased food utilization, growth, and resistance to infection are attained in diabetes by the use of insulin, he assumed that the vitamin might be exerting a similar action. Mills, therefore, tried the addition of vitamin B to the treatment of diabetes, and reports seven cases in which a definite effect seems to have been obtained. In five of these there was indisputable evidence of vitamin effect on sugar excretion; in another the clinical improvement was very marked; and the remaining patient left hospital when definite results were commencing to appear. Funk, Corbitt, and Collip, among others, have previously performed animal experiments in this connexion. Mills gives an acid-alcohol extract of plants rich in vitamin B, such as alfalfa, onions, and spinach. In diabetes the alcoholic extract was administered, but in the case of children the alcohol was evaporated and glycerin to 40 per cent. added as a preservative. The results in these cases indicate that vitamin B does possess the power of lowering sugar excretion, and 30 c.cm. of the extract were found to be roughly equivalent to 30 units of insulin. Without indicating diabetes as a deficiency disease, Mills believes that this therapy affords the injured pancreas an opportunity for functional recovery, and might in combination with insulin give better results than either would alone. It has the added advantage that oral administration is effective, and the treatment may therefore be carried on safely in the homes of patients to whom insulin could not be entrusted. In further experiments on dogs and rabbits as to the physiologic properties of this extract, Mills (*ibid.*, p. 384) found that it did not produce hypoglycaemia, and had no effect on the normal fasting blood sugar. It increases glycogen storage in the liver, but it has no insulin-like action on depancreatized dogs, nor does it enhance insulin action in such dogs. The author concludes that its effect is exerted directly on the pancreas, and that its action in inducing glycogen storage is secondary to its pancreatic effect.

**469. Malaria Therapy in Cerebro-spinal Syphilis.**

H. GOUGEROT (*Paris Méd.*, March 3rd, 1928, p. 198), discussing the malarial treatment of cerebro-spinal syphilis, remarks that patients who have contracted malaria after syphilis have nevertheless developed neuro-syphilis, including general paralysis of the insane and tabes dorsalis. Routine malaria therapy cannot be recommended in all cases as it is still under trial, and also a fatal case after inoculation with *Plasmodium vivax* has been recorded. He describes the case of a man aged 39 who contracted syphilis in 1916. In 1917 he contracted malaria and had many severe attacks until 1919. In spite of these he developed definite symptoms of early general paralysis. After intermittent anti-syphilitic treatment the patient was inoculated with malaria in March, 1927, and during the following month he had eleven malarial attacks; rapid and definite improvement followed, and five months later he returned to business. Gougerot thinks that this case shows that while previous malaria cannot prevent the development of neuro-syphilis, malarial inoculation has the power of arresting the progress of general paralysis, though this anomaly is difficult to explain. F. Dainville described the case of a man who contracted malaria and syphilis in 1916; he is now suffering from typical tabes dorsalis. MILLAN (*ibid.*, p. 200) doubts whether malaria prevents the development of neuro-syphilis; if it does so, the effect is not attributable to shock, nor to production of hyperpyrexia, but evidently to the production of antibodies. He cites the case of a man who contracted syphilis as a student. When approaching the age of 40 he developed serious cardiac symptoms. A prolonged but irregular course of anti-syphilitic treatment produced some improvement. Subsequently, he had a severe attack of enteric fever, and the cardiac symptoms disappeared completely; for three years he has been free from both heart disease and syphilis.

## Radiology.

### 470. Radiological Examination of the Bladder.

H. COHEN (*Med. Journ. and Record*, February 1st, 1928, p. 124) emphasizes the value, as a diagnostic method in bladder conditions, of introducing air in conjunction with x rays, by which means lesions are rendered demonstrable which would otherwise be overlooked; in many it is the only means of pre-operative diagnosis. The technique is said to be simple and free from danger under ordinary sterile precautions. After an ordinary skiagram of the bladder has been taken for comparison a soft rubber catheter is introduced and the urine drawn off; the bladder is then gently inflated with air by means of a hand bulb attached to the catheter, and the patient is then x-rayed again. Cohen does not use any device for measuring the amount of air introduced, but relies on the patient's feelings, though the Rubin apparatus used by gynaecologists can be employed. While foreign bodies are readily shown by the ordinary film this method, by making the proper contrast, assists in localizing the foreign body in the bladder and away from the rectum. The difficulty in visualizing tumours by an ordinary film owing to the want of comparison is overcome by this means, the air affording a contrast with solid tissue. Except in diverticulum of the bladder this method is said to give better results than those obtained by the use of sodium bromide or iodide solutions which, besides being expensive, tend to disguise pathological conditions in the bladder. In the case of a diverticulum, if the bladder is first distended with solution and x-rayed, the solution drained off, air introduced, and another x-ray photograph taken, the diagnosis will be easy—the diverticulum showing a white negative shadow, since, being devoid of muscular tissue, it retains the solution while the bladder shows a black air shadow. In the diagnosis of tumours washing out the bladder with bromide solution will leave a coating on the tumour.

### 471. X-ray Treatment of Asthma and Spasmodic Coryza.

P. VALLERY-RADOT, P. GIBERT, P. BLAMOUTIER, and F. CLAUDE (*Ann. de Méd.*, March, 1928, p. 214) believe that radical treatments, acting on the body generally, give more lasting results in asthma, and state that they have obtained excellent results from the employment of x rays. They recall that Schilling in 1906 was the first to use this method of treating asthma. Irradiations can be applied over the pulmonary hila, the spleen, or over both sites, either on the same occasion or alternately in successive treatments. The authors employ an induction-coil apparatus with a standard Coolidge ampoule, a focal distance of 30 cm., and an aluminium filter of 5 to 10 mm., and a dosage of 500 R. For both the lung and the spleen two ports of entry are used, anterior and posterior, in order to save the skin. Ten to twelve successive irradiations are given at the rate of two weekly. If no success follows, a second and even a third similar series may be tried. A summarized table showing the diagnosis, treatment, and results of sixty-four cases treated by this method is given. After a single prolonged irradiation nausea, vomiting, and sometimes a recrudescence of the affection have occurred, but these symptoms last only a few hours and are usually followed by marked amelioration. No other untoward symptoms were noted, and eosinophilia, a fall in the leucocyte percentage, and a lowering of arterial tension were never seen. Beneficial results have been reported following irradiation of several pulmonary areas and of other organs such as the thyroid, the cervico-thoracic ganglia, and the long bones. Many hypotheses as to the mode of action of the rays in these affections have been suggested. As Vidal and others have proved that an asthmatic is a colloidoclastic, the authors believe that the rays cause a change in the humoral state which prevents the production of colloidoclastic shock.

472. P. GIBERT (*Paris Méd.*, February 4th, 1928, p. 126) notes that the statistics of other workers show 30 per cent. of very good results, 35 per cent. of improvements, and 35 per cent. of failures in the treatment of asthma with x rays. In his own series of 64 cases of asthma and of spasmodic coryza either separately or in combination 19 patients seemed to recover completely, 16 were much improved, while the treatment failed in 29 cases. He advocates a dosage of 500 R twice a week, over a field of 12 by 12 cm. at a focal distance of 30 cm. with moderately penetrant rays. When there is spasmodic coryza alone he irradiates the spleen; in cases of asthma, with or without coryza, he irradiates the spleen and the hilar region. He does not conclude that the treatment has failed until he has given twelve irradiations. No untoward results have followed.

### 473. X Rays in Hyperchlorhydria.

SOLOMON (*Paris Méd.*, February 4th, 1928, p. 123) advocates irradiation with x rays for functional hyperchlorhydria, gastric or duodenal ulcer, and after gastro-enterostomy. He reports a representative case in each series in which he had obtained satisfactory results—namely, disappearance of pain and neurosis, fall in the acidity, absence of occult blood when previously present, increase of weight, and return of the capacity for work. He irradiates an abdominal field of 12 by 12 cm. or 16 by 16 cm. over the gastric area, at a focal distance of 30 to 40 cm. He uses penetrant rays (120 and 200 kilovolts) filtered through 0.5 mm. of copper and 1 mm. of aluminium. The dose at each irradiation is 500 R, repeated at intervals of three to eight days, until a total dosage of 5,000 R is attained. A second series of irradiations is given eight weeks later if the first has not been sufficient.

## Obstetrics and Gynaecology.

### 474. Ovarian Extract and the Menstrual Cycle.

FOLLOWING up Zondek's observation that the activity of ovarian extracts could be tested by their effect on the cyclical changes in the vaginal epithelium of the mouse, Mahnert and Slegmund concluded that the same hormone was produced in the ripe or ripening corpus luteum and in the corpus luteum of pregnancy, the difference being quantitative and not qualitative. Having found from animal experiments that folliculin was a satisfactory preparation, A. MAHNERT (*Wien. klin. Woch.*, March 8th, 1928, p. 329) tested its effects on the human menstrual cycle. Ten normal women, aged 21 to 33, were given five to ten subcutaneous injections of folliculin during the first two days of menstruation, six starting on the first day with 12 to 20 c.c.m. in all and four on the second day receiving a total of 8 to 10 c.c.m. of a preparation standardized in mouse units; in seven of these women menstruation was curtailed from the usual four or five days to two days or less. Mahnert considers that these results confirm the hypothesis that the period of repair of the endometrium during the menstrual cycle occurs when the ovarian follicular hormone secretion is at its maximum, and that the disintegration of the endometrium associated with the flow occurs when the hormone secretion is at its minimum. If the ovum from a ripened follicle dies early in the cycle, the follicle rapidly breaks down and the menstrual flow recommences after a shortened interval—that is, menstruation occurs with abnormal frequency. The inhibitory effect of injections of folliculin on the flow is ascribed partly to the regeneration of endometrium induced and partly to an effect on the uterine vessels. Similar injections were given to sixteen patients with functional abnormalities of menstruation, the flow being either excessive in quantity or duration, or there being disturbances of rhythm; satisfactory results were obtained in all but one. Mahnert concludes that an abnormal menstrual cycle due to delayed or inadequate ovarian secretion or early death of the ovum can be influenced by injections of the specific hormone present in folliculin.

### 475. Accidental Haemorrhage.

P. GAIFAMI (*Ann. di Ostet. e Ginecol.*, February 29th, 1928, p. 253) bases his account of premature detachment (before labour) of the normally situated placenta—so called accidental haemorrhage—on 400 unpublished cases collected from Italian and other sources. Of these 125 were at the author's clinic. He distinguishes between (1) asymptomatic cases, recognized by examination of the placenta; (2) severe cases with clamant clinical signs and accompanied by diffuse haemorrhagic lesions of the myometrium and adnexa (ntero-placental apoplexy); and (3) cases of an intermediate degree of gravity; these last form the majority. The apparent incidence of the morbid condition varies with the sharpness of the watch which is kept for it: the mean figure is roughly 0.22 per cent. Albuminuria was noted in 80 per cent. of the cases; eclampsia was present in 6 per cent. of Gaifami's cases. Only about one patient in five is a primipara. Several clinics have reported an increasing frequency of accidental haemorrhage during recent years. The foetal mortality is given as 80 per cent., and cadaveric rigidity is stated to be frequently noted when the foetus is delivered. Diagnosis by the practitioner or midwife is said to be infrequent, most cases being confused with placenta praevia; it is nevertheless important that detachment of the normally-situated placenta should be recognized before external bleeding, combined with a state of shock, has rendered the patient's condition desperate. The chief signs are (1) progressive increase in size of the uterus, which is tense and tender, (2) acute pain localized in one portion of the uterus, (3) loss of blood-stained serous

discharge, (4) tenuity of the bag of membranes, and (5) irregularity of the uterus in the neighbourhood of a retro-placental haematoma. Utero-placental apoplexy may be present in cases in which hardness and tenderness of the uterus are slight or absent, but is always accompanied by grave general signs. About one-half of cases require no operative intervention, but there is always considerable danger that post-partum haemorrhage may follow. In hyper-nate cases in which the patient is too ill to be taken to hospital stimulants should be given, an abdominal binder applied, and perhaps pituitary or adrenal extract injected. Vaginal tamponade is not to be recommended, but rupture of the membranes may sometimes be justifiable. Accouchement forcé with metallic dilators is now superseded by vaginal or abdominal Caesarean section, which offers the only hope of cure in grave cases. The author reports a mortality of 14 per cent. in the abdominal and 22 per cent. in the vaginal operation. Pro-Caesarean hysterectomy has been largely adopted for these cases in Italy, chiefly on account of fear of grave post-partum haemorrhage if the uterus be left behind, but British statistics are taken to be reassuring in this respect. The decision whether hysterectomy should be performed calls for careful judgement, which should take into account the patient's general condition, the contractility of the uterus and its degree of morbidity as revealed during the operation, the patient's prospects of maternity, and the nature of the therapeutic essays to which she has been previously subjected.

#### 476. Urea in the Treatment of Uterine Bleeding.

P. WERMER (*Zentralbl. f. Gynäk.*, March 17th, 1928, p. 693) reports the treatment of 46 women, aged from 16 to 50, suffering from excessive uterine bleeding, by administration twice daily of 20 grams of urea dissolved in water. Myoma and other gross morbid conditions of the uterus were absent from the series, which consisted mostly of patients with ovario-genous bleeding, but contained some cases of bleeding due to acute or chronic adnexal inflammation and one or two of climacteric haemorrhage. In 27 cases the bleeding was arrested, in 6 diminished: as a rule, five doses—that is, two days' treatment—were required, but a transitory favourable effect was noted after the first powder had been taken. According to Wermer the effect of the urea is due indirectly to its diuretic action; the organism responds to the increased elimination of water by increased production of the hormone of the posterior lobe of the pituitary gland; the pituitary hormone, secreted to counteract diuresis, exercises incidentally a utero-haemostatic function. Wermer has had similar results from intravenous injections of certain other diuretics, some of which, however, are known to increase the coagulability of the blood, a function which urea does not appear to possess. Uterine bleeding has been reported by Vogt and others to be influenced favourably by injections of lusu-lin, and in this connexion Wermer refers to Dixon's discussion of the action of pituitary extract (*British Medical Journal*, 1927, vol. ii, p. 1070).

### Pathology.

#### 477. The Cerebro-spinal Fluid in Tuberculous Meningitis.

D. STEWART (*Edin. Med. Journ.*, March, 1928, p. 141), referring to the difficulty of early diagnosis of tuberculous meningitis in children, points out that examination of the cerebro-spinal fluid affords the most accurate means which we at present possess of distinguishing between this condition, the meningism of acute infections, and other types of meningitis and ocephalitis. The value of early examination of the cerebro-spinal fluid is borne out by a case in which a diagnosis of tuberculous meningitis and a hopeless prognosis had been based upon adequate symptomatic data, though the cerebro-spinal findings showed no increase in cell count or protein and no organisms; at the end of a fortnight, however, complete recovery resulted. The fluid may be withdrawn either by lumbar or cistern puncture, the latter route being as safe and as easily performed as the former, except in the very late stages of the disease when acute hydrocephalus causes brain displacement. In a series of thirty cases the cell count was increased in all, and the differential count showed a lymphocytosis of from 80 to 98 per cent.; the total protein was definitely increased in twenty-five. The estimation of the chlorides and sugar gave such variable results as to render it of no diagnostic importance, the significant data being furnished by qualitative and quantitative protein examination and enumeration of the cells, including the valuable differential count. Tubercle bacilli were found in the cistern fluid in all cases, and in the lumbar fluid in 57 per cent. Stewart concludes that in every case of doubtful tuberculous meningitis the cerebro-spinal fluid should be examined qualitatively and quantitatively for increased pro-

tein as early as possible; any increase in the cell count should be noted, and a search be made for tubercle bacilli in the cistern and lumbar fluids.

#### 478. Calcium Deficiency as a Cause of Disease.

CITING an important experiment performed by Steenbock and Hart on the calcium metabolism of a goat, C. E. CORLETTE (*Med. Journ. of Australia*, February 18th, 1928, p. 198) discusses fully the pathology of various diseases of animals and birds which are caused evidently by a calcium deficiency. He concludes that in calcium deficiency there is a general disorder involving all the functioning cells and important organs of secretion. Diseases such as rickets, gastro-intestinal catarrh, bronchitis, and diarrhoea, represent a process going on in the liver, pancreas, kidneys, thyroid, parathyroids, and other organs, the functions of which become disordered and depressed. The glycogenic function of the liver is disturbed, its detoxicating function is more or less suspended, and metabolic poisons may not be properly neutralized. These organs and also the nervous system do not always recover completely when the original deficiency is removed, and some permanent damage often remains. Thus coeliac disease in children and cirrhosis of the liver in adults may be the result of a deficiency no longer existing in the diet. Corlette believes that calcium and/or phosphorus deficiency can cause nervous disorder closely resembling that produced by deficiency of vitamin B, and that it is, or may be, implicated in many morbid conditions of man and animals in which nervous symptoms often occur.

#### 479. Influence of Hydrogen-Ion Concentration on Cellular Division.

R. REDING and A. SLOSSE (*C. R. Soc. de Biologie*, March 23rd, 1928, p. 878) have performed some experiments on the effect of peptone shock in altering the hydrogen-ion concentration of the blood and in stimulating cell division. Dustin found in the mouse that under the influence of peptone shock there was evident nuclear destruction on the first day, followed on the third or fourth day by a very active wave of karyokinesis; the mitoses were observable not only in those organs such as the lymphatic glands, intestinal mucosa, and thymus in which they can normally be found, but also in others in which they are seldom seen. The authors' experiments were performed on six dogs; in eight experiments peptone shock was produced and in one experiment anaphylactic shock was caused by means of horse serum. The hydrogen-ion concentration of the blood was measured by Hasting and Sandroy's method. In cases of peptone shock the hydrogen-ion concentration fell from pH 7.42 to pH 7.20; the return to normal occurred rapidly, generally in a few hours. But forty-eight hours after the shock the hydrogen-ion concentration commenced to decrease, so that on the third and fourth days it was about pH 7.48; after this it again returned to normal. Histological observations showed that the primary fall of pH was accompanied by nuclear destruction; and that the wave of alkalinity on the third and fourth days was accompanied by a prolonged wave karyokinesis. The authors therefore consider that the activity of the cellular division is determined by the alteration in the hydrogen-ion concentration of the blood. Even when no actual shock was apparent after the intravenous injection of peptone marked alterations in the hydrogen-ion concentration occurred.

#### 480. The Filterable Form of the Tubercle Bacillus.

A. CHARLOTTE RUY (Nederl. Tijdschr. v. Geneesk., February 18th, 1928, p. 795), in a review of the literature dealing with the existence of a filterable form of the tubercle bacillus, states that the opinions of the French investigators cannot be regarded as conclusive. Two views may be held on this subject. The first is that the pathogenic tubercle bacillus may produce a filterable form which may be transformed again into the typical bacillus. The second is that the pathogenic tubercle bacillus can produce a virus which differs from the original tubercle bacillus as regards pathogenicity, form, and other properties, and is a filter passor. A number of French observers have based the existence of such a virus on the following considerations. (1) The presence of acid-fast bacilli in the tracheo-bronchial glands of guinea-pigs inoculated with filtrates containing tubercle bacilli without typical inoculable tuberculosis developing; (2) a positive tuberculin reaction in these animals; (3) the death from cachexia of a number of those animals. Ruy, however, brings forward the following objections. A number of investigators have been unable to find acid-fast bacilli resembling tubercle bacilli, and no control examinations were made on normal animals. A positive tuberculin reaction can be explained as a reaction to extracts of tubercle bacilli which were introduced with the filtrates. The death from cachexia may have been due to the large quantity of the filtrates introduced.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 481. Endemic Meningococcal Meningitis.

S. McLEAN and J. P. CAFFEY (*Amer. Journ. Dis. Child.*, March, 1928, p. 357) describe the protean nature of the clinical manifestations in 136 cases admitted to hospital from 1914 to 1926; 17.6 per cent. of the patients were not over 3 months old and 67.6 per cent. were in the first year of life. Crowding, poverty, and poor hygiene are predisposing causes. Muscular rigidity, especially at the level of the neck, with or without retraction of the head, was present in 84.5 per cent. of the cases, and is the most frequent and important single clinical sign. Increase of tendon reflexes—Kernig's and Brudzinski's signs—though often present, are unreliable diagnostically in infants. Unexplained irritability (62.5 per cent.) and drowsiness, stupor, or coma (46.2 per cent.) are of value in focusing attention on the central nervous system. Examination of the cerebro-spinal fluid is essential when there is a bulging fontanelle. Convulsions were present in 29.4 per cent. of the patients, generally at the onset of the disease; 11 per cent. had a haemorrhagic eruption, meningococci being demonstrable in blood films made from the purpuric areas. The most frequent ocular manifestation was strabismus, which was present in 20.5 per cent. of the cases. The temperature, vomiting, and tache cérébrale are not characteristic. The need for lumbar puncture in suspected cases is emphasized. The presence of a purulent fluid nearly always indicates meningococcal meningitis; the discovery of meningococci makes the diagnosis certain. Blood cultures should be made in all cases, but particularly in the fulminating ones, when organisms can be recovered from the blood, though they are not demonstrable in the cerebro-spinal fluid.

### 482. Thoracic Signs of Hypertension.

S. WEINSTEIN (*Med. Klin.*, March 16th, 1928, p. 418) confirms the observations of Delherm and Chaperon that hypertension is frequently associated with dilatation of the aorta. Among 100 patients (42 men and 58 women) 18 (4 men and 14 women) had hypertension and 23 (10 men and 13 women) had aortic dilatation. Further analysis showed that 50 per cent. of these 18 patients who had hypertension had also aortic dilatation, as compared with 17 per cent. in whom this condition was associated with a normal or slightly increased blood pressure; 39 per cent. of patients having aortic dilatation had hypertension, while only 12 per cent. of those in whom the aorta appeared to be normal had hypertension. Weinstein states also that there is a direct relation between the size of the lungs and the blood pressure. In collaboration with W. Lutz he has investigated clinically a number of cases by means of skiagrams; it was found that a subnormal development of the lungs was very often associated with hypertension. The two authors also investigated the pulmonary development of 100 patients; of these, 31 (8 men and 23 women) had small lungs. Among these, of 18 patients having hypertension 13 had small lungs, while among 82 patients who had normal or slightly raised blood pressure only 18 had small lungs. Among 31 patients who had small lungs 13 had hypertension, while among 69 patients who had lungs of normal size only 5 had hypertension. Among 116 women over 50 years old 52 per cent. with small lungs had hypertension, in contrast with only 6 per cent. of "control" cases; 86 per cent. of women having hypertension had small lungs, as compared with 25 per cent. of women who had normal or slightly raised blood pressure. Weinstein draws the following conclusions. (1) The aortic dilatation described by Delherm and Chaperon and its connexion with hypertension has been proved in a considerable number of cases. (2) The size of the lungs should be estimated systematically, as hitherto this question has not been considered. Small lungs, especially in women, stand in close relation with hypertension. (3) One or both symptoms (aortic dilatation and small lungs) were present in all cases of hypertension; when both symptoms were absent there was no hypertension.

### 483. Latent Syphilis Carriers and the Spread of Infection.

W. KOLLE (*Zentralbl. f. Bakt.*, 1928, vol. 106, Festschrift, p. 134) asks why it is that with the widespread employment of salvarsan in every country syphilis has not been practically stamped out. For it is known that salvarsan rapidly causes every symptom of the disease to disappear, and that it leads in a high proportion of cases treated early to a lasting cure. It is admitted, on the other hand, that the majority of patients

treated with salvarsan, although they show an immediate apparent cure, yet relapse and again become infective, but it is difficult to believe that all cases of syphilis originate from contact with cases of open infection. Many patients are found to be syphilitic during the course of routine examination who never suspected it themselves; this applies especially to patients with disease of the nervous or arterial system. The author thinks that these patients have become infected with syphilis without ever developing primary manifestations. His suggestion is that a large number of persons with latent syphilis are in reality chronic carriers of the disease, and that they may prove infective in much the same way as an apparently healthy person may excrete typhoid bacilli. He thinks it possible that these persons are carrying living spirochaetes on their mucosae without showing any evidence of disease. Animal experiments tend to support this view. Albrecht has shown with rabbits that a primary chancre of the vulva undergoes spontaneous cure; but when does that have recovered completely from such a chancre are brought to a huck, the huck develops syphilis without, however, showing any primary manifestations; the infection can be demonstrated by extirpation of the regional glands and injection of them into fresh animals. A symptomless infection can also be produced in the mouse, as the author has shown. After infection, the spirochaetes live in the glands, spleen, and brain for several months; they can easily be demonstrated by inoculation into fresh mice. The author doubts whether there is any immunity in syphilis other than an infection immunity. If this is so, and if syphilis can be imparted by apparently healthy persons who are carriers of the disease, the only hope in the cure of syphilis is the earliest possible treatment so as to obtain a chemical sterilization and thus prevent the development of the carrier condition.

### 484. Pluriglandular Syndrome following Mumps.

J. HUBER (*Bull. et Mém. Soc. Méd. Hôp. de Paris*, March 8th, 1928, p. 368) records the case of a man, aged 26, who, after a severe attack of mumps complicated by unilateral orchitis followed by atrophy of the left testis, developed a pluriglandular syndrome consisting in sexual frigidity, hypotrichosis, and upper dorsal kyphosis indicating overaction of the suprarenals and hypophysis respectively, together with general weakness and diffuse pain most marked in the lumbar region and sacrum, suggesting an involvement of the sympathetic system. No benefit was derived from opotherapy.

## Surgery.

### 485. Results of Periarterial Sympathectomy.

S. RUBASCHOW (*Zentralbl. f. Chir.*, March 24th, 1928, p. 727), who reports 46 cases of periarterial sympathectomy, believes that this procedure should not be abandoned; it may give good results in certain diseases. The operation affects chiefly the trophic nerve fibres and not the vasomotor fibres. He has had very good clinical results in three cases of causalgia, and in two cases of amputation the stumps remained entirely free from trophic changes. In Raynaud's disease three out of four patients with injuries of the sciatic nerve remained free from ulceration. In twelve cases of ulcers due to various causes cure was obtained in six. Among ten cases of spontaneous gangrene two patients improved; in six cases the operation had no effect and two patients became worse. In two cases of ununited fracture some improvement resulted in one case. The operation failed in a case of syringomyelia, in five cases of tuberculous arthritis, and one case of elephantiasis. The author states that moist gangrene occurred in two of the cases which did not improve. He considers that periarterial sympathectomy is advisable only in cases showing "dry" gangrene. One patient with causalgia remained cured after three and a half years, another with a gunshot wound of the sciatic nerve relapsed after three years. In a case of early gangrene of the little toe improvement has persisted for more than two years. In a typical case of Raynaud's disease of the hand there was no immediate result, but after two or three months considerable improvement resulted. No case became septic. In femoral sympathectomy the author operates on the middle third of the artery below the origin of the profunda artery and the lymph glands. In one case the brachial artery was injured and required ligature, but the ultimate result was satisfactory.

Occasionally post-operative arterial hyperaemia persisted, in one case (incipient spontaneous gangrene) for two years with good result; in two other cases (causalgia and trophic ulcer) it lasted for three years. Rubaschow does not think that hyperaemia is the preponderant factor in the healing process; in a case of ulcer of the foot to a lowing a gunshot wound of the sciatic nerve, the operation was followed for two weeks by anaemia and coldness of the foot, possibly arterial spasm, yet during this period the ulcer healed. In the course of the following two years there was intense hyperaemia and no recurrence. In another case an ulcer reappeared after three years, in spite of persistent hyperaemia. In one case of digital ulceration (thrombo-angiitis obliterans) the whole right arm was pulseless. Brachial sympathectomy with resection of 2 cm. of the artery was performed; this was followed by hyperaemia and uninterrupted healing of the ulcers of the fingers.

#### 436. Diabetes Complicating Surgical Urinary Conditions.

I. CHIOFALO (*Journ. d'Urol.*, January, 1928, p. 11) discusses the pre-operative treatment of surgical urinary disease associated with diabetes. When the case is not urgent; as, for example, in prostatectomy, it is usually sufficient to reduce the carbohydrates, thus producing a condition of tolerance so that the glycosuria disappears. In such cases insulin is of no use and patients can be satisfactorily prepared for operation without its employment. When there is marked acidosis it is necessary to employ a strict diet combined with insulin. The results in these cases are said to be excellent, and the operation can be performed with little or no risk. It will be necessary to inject 15 to 20 units of insulin one and a half hours before operation, followed in half an hour by a small quantity of sugar. Morphine may also be given with advantage. Chloroform is absolutely contraindicated, and local anaesthesia, ether, or spinal anaesthesia should be used. In urgent cases a dose of 40 to 50 units of insulin should be given an hour before the operation, followed by 50 grams of sugar. Insulin is given in all cases after the operation; the results so obtained are said to be excellent and frequently to result in cure.

#### 437. Chronic Appendicitis.

H. KOSTER (*Archives of Surgery*, January, 1928, Part I, p. 44) argues that while dull aching pain or intermittent and colicky pain in the right lower quadrant of the abdomen may be referable to organic or functional disturbances in the appendix, it is not correct to group all the conditions of the appendix under the heading "chronic appendicitis." In many of these cases the pathologist may not find any evidence of chronic inflammation, the symptoms having resulted from kinks, adhesions, and strictures. He suggests that the term "chronic appendicitis" should be replaced as a pre-operative diagnosis by "appendicular colic." This will have a definite meaning and a distinct application as a working basis. No two pathologists agree as to the criteria for the diagnosis of chronic inflammation, and the result has been confusion and controversy. Koster thinks that with the acceptance of definite criteria such confusion will be avoided.

#### 438. Symmetrical Gangrene of the Extremities following Typhoid Fever.

C. IMPERIALE (*Rif. Med.*, March 5th, 1928, p. 242), who records an illustrative case, states that of all the numerous infectious diseases followed by gangrene of the extremities typhoid fever occupies the first place. Of 102 cases of post-infective gangrene collected by Barraud, 44 were due to this cause. Predisposing causes include cold and damp, excessive physical exertion, and pre-existing diseases such as syphilis, nephritis, diabetes, arterio-sclerosis, alcoholism, and indulgence in tobacco. As a rule the lower extremities are affected, the right as often as the left, but the simultaneous appearance of gangrene in both is rare. The upper limbs are seldom affected. Post-infective symmetrical gangrene presents a characteristic clinical picture in that the onset is sudden and the progress rapid and extensive. The condition can readily be distinguished from Raynaud's disease, in which there is a long prodromal period and a certain periodicity of the symptoms. As regards the pathogenesis, post-typhoid gangrene is usually due to arterial thrombosis, with which may be associated vascular spasm of sympathetic origin. The prognosis is grave, the mortality being about 50 per cent. The present case was that of a soldier, aged 20, who developed gangrene, first in the right leg and shortly afterwards in the left leg, about a month after the onset of an ordinary attack of typhoid fever. Amputation on the right side was performed in the middle half of the thigh, and on the left leg at the upper third of the leg. Recovery followed. Examination of the arteries in the amputated limbs showed thickening of the intima and the formation of a thrombus.

## Therapeutics.

#### 439. Alcohol in Acute Infectious Diseases.

J. D. ROLLESTON (*Brit. Journ. of Inebriety*, April, 1928, p. 201), continuing his observations on this subject (see *Epitome*, April 23rd, 1927, para. 451), states that during the year 1927, when the annual consumption of brandy at his hospital was only 25½ oz., as compared with 991½ oz. in 1926 and 2,539 oz. in 1925, no brandy whatever was used in the treatment of diphtheria, the case mortality from which was the lowest recorded at his hospital (3.01 per cent.) though the type of disease remained the same. He maintains that the use of brandy, in spite of the evidence of its inefficiency or harmfulness, is doubtless often due to the pressure exercised upon the doctor by the patients' friends, who are under the mistaken impression that in the absence of such treatment everything is not being done that can be to save life or hasten recovery. Such influence, though much more likely to be brought to bear successfully in private practice than in institutions, is not without its effect even in hospital. In addition to the reduction in the administration of alcohol in the wards Rolleston has exercised a strict control over its use in the ambulance service connected with his hospital, the nurses on ambulance duty having received orders to furnish a report of every case in which they considered such administration necessary, together with the amount given. The result of this measure was that during the whole of 1927 only 1 ounce and 7 drachms of brandy was used by the ambulance nurses. This figure applied not only to the 3,223 patients admitted to the hospital in the course of the year, but to all the other cases removed by the ambulance nurses, amounting to a total of over 12,000 persons conveyed and a mileage of over 68,000.

#### 440. Saline Solutions in Hypertension.

W. L. T. ADDISON (*Canadian Med. Assoc. Journ.*, March, 1928, p. 281) summarizes previous research in arterial hypertension as showing that calcium chloride produces an inorganic acidosis, with increased excretion of ammonia and soda; potassium chloride, without change of the acid-alkali ratio, gives an increase of soda secretion; potassium citrate produces an alkalosis with an increased soda excretion; and all three drugs with proper dosage reduce arterial pressure in the large majority of cases. Consequently Addison investigated the reaction of potassium and sodium chlorides in the same person, and the experiments were repeated with the respective bromides, lest the chloride should be thought to be a party to the action. Tests were made upon five patients, all of whom were on a salt-poor diet with fish once daily and vegetables, fruits, cereals, and milk freely, but from which meat, poultry, eggs, cheese, beans, peas, and nuts were excluded. Addison prescribes a mixture of potash salts—namely, potassium bromide 10 grains, potassium chloride 20 grains, potassium citrate 30 grains, with syrup to half an ounce, to be taken in water after food. This formula acted well in certain cases when the chloride acted indifferently, the potassium bromide and citrate being among the most efficient of the potash salts in reducing hypertension, while the inclusion of potassium chloride assists the stomach and kidney functions. The investigation showed that the giving of all three potassium salts causes a fall in blood pressure with an amelioration of symptoms of hypertension, while the administration of sodium chloride and bromide is associated with a rise in blood pressure and an increase of the symptoms of hypertension.

#### 441. Prolonged Salicylate Treatment in Rheumatic Endocarditis.

A. COURY (*Bull. Soc. de Théor.*, February 8th, 1928, p. 51), who records two illustrative cases in children aged 13 and 7 years respectively, protests against the view that salicylate treatment is needed in acute rheumatism only so long as the joint affection lasts, and that it has no effect in cardiac complications. Numerous writers in France and other countries have shown that acute articular rheumatism is a disease with a very prolonged course, and in essence cardiac rather than articular. During the last ten years Coury has continued to treat his rheumatic patients for at least a year after all the joint manifestations had disappeared. This treatment comprises the administration of salicylates for from fifteen to twenty days a month with ten to fifteen days' rest, and in much smaller doses than are required for the acute attack of rheumatism. Coury's two cases show that rheumatic endocarditis can clear up entirely over a long time after it has been established. The large doses of the acute stage were not needed, no more than from 2 to 5 grams daily being required. In prolonged salicylate treatment two factors must be considered. Gastric intolerance is more likely to occur when the treatment is prolonged than when the drug is given

in large doses for a few days only. The second factor is habituation, which rapidly evokes resistance of the rheumatic virus to specific treatment. Coury recommends intravenous injections of 2 or 3 grams of salicylates in glucose solution two or three times a week.

#### 492. Sublingual Absorption of Drugs.

D. DAVIS and D. AYMAN (*Arch. Intern. Med.*, February 15th, 1928, p. 231) conducted investigations in order to determine the absorption capacity of the sublingual mucous membrane for drugs. A known quantity of morphine sulphate was placed beneath the tongue, and after a given time the contents of the sublingual space were washed out and the exact amount of unabsorbed drug was determined. The authors found that no appreciable absorption occurred in seven experiments in which 10 to 15 mg. of powdered morphine sulphate were placed under the tongue for from five to ten minutes, 65 to 80 per cent. of the drug being recovered. Allowing for loss in recovery less than 10 per cent., if any at all, of the total drug was absorbed. There is no evidence from the literature in support of any capacity for absorption by the sublingual mucous membrane at all comparable with the rapid absorption capabilities of the gastro-intestinal and rectal mucous membranes, and the authors consider that this method of administering morphine should be discontinued.

#### 493. Treatment of Erysipelas.

O. KRAUS (*Med. Klin.*, February 24th, 1928, p. 294) records 45 cases of erysipelas in adults, 15 of whom were treated with intragluteal injections of milk, 15 with diphtheria antitoxin, and 15 with local applications such as ichthyol ointment, Burrow's solution, or tincture of iodine. The results were as follows: Rapid recovery occurred after the injection of 5 c.cm. of milk which had been sterilized for ten minutes in a water bath. An equal dose of diphtheria antitoxin was not nearly so efficacious. Local treatment did not essentially shorten the course of the disease. The only contraindication for milk injections is the presence of pulmonary tuberculosis or chronic recurrent haematemesis.

#### 494. Autohaemotherapy in Conjunctivitis.

A. DE CAMPE (*La Pediatria*, March 1st, 1928, p. 225) publishes brief details of thirty-one cases of conjunctival and corneal affections in children, treated by injections of 5 c.cm. of whole blood into the gluteal muscles. The injections were given every other day or twice a week, and the results were excellent, for in 78 per cent. of the cases cure was obtained, although most of the inflammations were chronic in type. Improvement showed itself in the rapid disappearance of irritation, photophobia, blepharospasm, and corneal infiltration. No general reactions were observed after the injections. The author thinks that they may act like non-specific proteins, or produce their effects by stimulating the sympathetic system.

## Laryngology and Otology.

#### 495. Mucocoele of the Accessory Nasal Sinuses.

According to C. A. HEATLY (*Arch. of Otolaryngol.*, February, 1928, p. 150) mucocoele of the accessory nasal sinuses is not the rarity which it has frequently been considered. He defines it as an accumulation and retention within a sinus of a mucoid secretion, owing to continuous or periodic closure of its ostium, and resulting in gradual thinning, distension, or actual erosion of one of its walls. The onset of the disease is so gradual and the course so slow and painless that the etiology is difficult to establish, though cases have been recorded in which catarrh, trauma, or osteoma appear to have been the exciting cause. As a rule the first sign is swelling in the orbital region. This usually occurs in the upper inner angle of the orbit, and as a result the eyeball is displaced downwards and outwards. Exophthalmos and diplopia may occur and epiphora may be an early and misleading symptom. The swelling may involve the anterior wall of the frontal sinus, and in ethmoidal mucocoeles nasal obstruction, or actual deformity, may be present. There is usually no local tenderness, the swelling may be as hard as bone, or may yield a parchment-like crepitation. If actual erosion of the wall of the sinus has taken place a fluctuating tumour may be felt, protruding through the bony defect. The absence of nasal discharge is characteristic, although the duct is not completely closed in all cases. The content of the mucocoele varies greatly in colour and consistency. Usually it is a brownish, thick fluid, but may be clear and serous in character. Treatment should aim at establishing a large permanent communication with the nose. In some cases, especially where the mucocoele is confined to the ethmoidal labyrinth, a simple intranasal opening will suffice,

but in the majority of cases an external operation is necessary. In addition, a large drainage tube is passed from the sinus into the nose and left in position for several days. Prompt subsidence of orbital symptoms usually follows operation.

#### 496. Lesions of the Cervical Sympathetic Ganglion and the Pericarotid Sympathetic.

LASAGNA (*Arch. Ital. di Otol.*, January, 1928, p. 1) has performed a series of experiments on the cervical sympathetic apparatus in rabbits, employing three types of operation. In the first he removed the sympathetic trunk with the three cervical ganglia of one side; in the second, in addition to this, he also excised the pericarotid plexus of the same side; and in the third case he merely removed the carotid plexus. The animals were killed at periods of a few hours, a few days, a month, two months, and so on, and examinations were made of the turbinate bodies and their mucosa, the laryngeal mucosa, and the wall of the carotid vessel. It was found that the nasal and laryngeal mucosa were congested with dilated vessels, and that the glands became engorged and secreted a copious mucous fluid with which the ducts were dilated. In the cases where the pericarotid sympathetic was removed there was an oedematous infiltration of the submucous layer, but not where the ganglionated trunk only was removed. These changes were found only in those animals which were killed soon after the experiment. The longer the period between the experiment and the microscopic examination the more nearly had the tissues returned to normal, until at the end of a month there were practically no pathological changes to be seen. Removal of the ganglionated trunk and the pericarotid plexus had a greater effect, which lasted longer than that produced by removal of the trunk alone. Removal of the plexus alone had about the same effect as the removal of both systems. Examination of the carotid revealed a reduction of the lumen, an overgrowth of the muscular coat, and a copious formation of connective tissue in place of the extirpated tunica adventitia, which showed that new sympathetic fibrils appear. The conclusion is that extirpation of the cervical sympathetic system produces an engorgement of the nasal and pharyngeal mucosa, but that its duration is too short to be of any therapeutic value in such cases as atrophic rhinitis and ozæna.

#### 497. Laryngeal Cough.

G. FERRERI (*Arch. Ital. di Laringol.*, December, 1927, p. 5) discusses the causes and significance of the various types of cough. From an etiological point of view he classifies cough according as it is due to a laryngeal lesion or secondary to conditions of the central nervous system, the air passages, including the upper and lower respiratory tract, the alimentary tract, and general body diseases, such as diabetes and albuminuria. The type of cough is often a useful diagnostic sign in children, especially in the harsh raucous cough of measles and scarlatina and in whooping-cough. In some cases of tracheo-bronchial adeopathy there are frequent attacks of convulsive cough, but these two types can be distinguished by symptoms of pressure on the bronchi—an asthmatic wheeze in many cases. In cases of laryngeal papilloma there is some alteration in the voice besides the cough. In adults the persistence of a raucous cough may be of considerable gravity in the exanthemata, since it may signify the onset of ulceration of the mucosa. In influenza laryngitis the superficial ulceration of the cords is accompanied by a violent metallic cough. Benign growths of the larynx cause short attacks of violent cough, but the cough in malignant disease has no diagnostic value. In tuberculous laryngitis the cough is more noticeable in the pachydermatous type than in the ulcerative or the oedematous. The brassy cough of laryngeal paralysis is very typical, and each of the various affections of the larynx and trachea has a particular variety of cough which gives indications as to its origin.

## Obstetrics and Gynaecology.

#### 498. Late Sequels of Induced Abortion.

SERDUCOFF (*Gynæcol. et Obstet.*, March, 1928, p. 196), in the light of his experience in Russia, where abortion for social reasons has been authorized since 1920, describes the harmful effects which are produced in women who have undergone one or several artificial interruptions of pregnancy during the early months. He is satisfied that in young women aged 17 or 18 artificial abortion, even when unaccompanied by inflammatory phenomena, is followed by intractable sterility. In older subjects a morbid involution of the genital organs ensues, which takes three main forms—infantile fibro-atrophic uterus, small atrophic uterus, and fibro-metropathic uterus,

which may be associated with fibro-cystic ovarian degeneration. In certain instances psychic instability, hypo-ovaria, obesity, frigidity, dyspareunia, and various hysteroneuroses are also noted; these, together with the atrophic uterine changes, may be attributed to the sudden disturbance by artificial abortions of the endocrine activity of corpus luteum, placenta, ovum, uterus, etc. In three cases out of four artificial abortions are followed by oligomenorrhoea, in one out of ten by amenorrhoea. Serdukoff quotes the observations of his co-worker Lankovitz, who, comparing the confluents of 1,700 women who had not undergone abortion with those of 660 who had had from two to four or more artificial abortions, found that in the latter series pyrexia was three times as frequent as in the former, duration of labour was three times as great, low placental insertion was three times as common, difficulty in placental detachment was twice as frequent, and retarded involution of the uterus was four times as common.

#### 499. Treatment of the Menopause.

P. E. MORHARDT (*La Vie Méd.*, April 10th, 1928, p. 427) discusses recent views on the causation and treatment of the various disturbances associated with the menopause. It is supposed that the less normal the sexual life of a woman has been the more troubles she has at the menopause. It is stated that the more primitive woman or less disturbed than civilized women. The hot flashes felt when the blood of the splanchnic area arrives rapidly at the periphery are attributed to the loss of the vagotonic action of the ovaries. There is a profound modification in the relations between the two antagonistic systems, vagotonic and sympathicotonic, due to the functional disappearance of the ovaries. The question whether the obesity so frequently noticed at this time is associated with a modification of the basal metabolism has not been satisfactorily settled, as hypo- or hypothyroidism may be simultaneously present. The author thinks it reasonable to suppose that the removal of the ovarian secretion will upset the endocrine equilibrium, and many of the symptoms may be due to this. The psychic phenomena are said to be more marked in the unmarried and in widows. Nothing has yet been found which replaces the effects which the ovarian secretion exerts on the nutrition of the articular cartilages and capsules. The author places psychotherapy first in his consideration of treatment, then the various ovarian preparations. As a sedative he recommends two tablets of a day of potassium bromide 30 to 40 grains, codine phosphate 40 eg., extract of valerian 6 grams, syrup of bitter orange peel 200 grains, water q.s. to 300 c.c.m. Local symptoms such as hemorrhoids he treats with charcoal, and pruritus with dermatol 50 eg., boric acid 1.5 grams, tannin 1 gram, vaseline 30 grains. For acne rosacea cold cream, with the addition of adrenalin (2 per cent. of the 1 in 1,000 solution), has proved useful.

#### 500. Fibroma and Pregnancy.

LUTAUD (*Bull. et Mém. Soc. Chir. de Paris*, March 2nd, 1928, p. 168) reports a case of a three months' abortion in a multipara who had previously given birth to two healthy children. On curettage being attempted a fibroma, the size of a large orange, was discovered attached to the posterior uterine wall, this being evidently the cause of the abortion. Myomectomy was advised but refused, and on examination some time later it was found that the tumour had undergone marked regression. A subsequent pregnancy terminated normally at full term. Two years later, after strong pains simulating labour pains, a hard tumour as large as a foetal head was passed into the vagina and was easily removed. During the following three years the patient has enjoyed excellent health, and monthly examinations have revealed no abnormalities. Lutaud observes that other similar cases have been reported in which an increase in size, during pregnancy, of a fibroma by oedematous infiltration has been followed after labour by a regression or pseudo-regression of the tumour.

#### 501. Fracture of the Clavicle during Spontaneous Labour.

K. ADLER (*Zentralbl. f. Gynäk.*, April 7th, 1928, p. 879) examined a series of 2,000 infants (1) at the time of their spontaneous delivery by vertex presentation, (2) at the date of their discharge from an obstetric clinic. One case only of fracture of the clavicle was found; the mother was a 4-para, aged 35, and the child weighed 4.3 kilograms. A fracture of the anterior clavicle was audible as the perineum was being supported for passage of the shoulders; subsequently the usual physical signs were readily recognizable. Of the infants in this series 603 were examined radiologically for missed clavicular fracture. According to reports in the older literature fracture of the clavicle after spontaneous vertex delivery appears to have been at one time rather frequent.

854 D

Riother in 1902 reported 65 cases during one year at a Vienna clinic; Munst year later reported an incidence of 1.3 per cent. among 1,600 cases at Copenhagen, and Hanch (1905) an incidence of 0.67 per cent. among 2,500 spontaneous vertex deliveries. Certain of the older writers believe that the fracture occurred during birth of the shoulders, others ascribed it to an intrapelvic injury. It was agreed that diagnosis was difficult for the reason that crepitation, unusual mobility, and impaired function were frequently absent. It was invariably noted that the anterior clavicle was the more frequently fractured.

## Pathology.

#### 502. Bacteriology of Septicaemia of Childbirth and Abortion.

K. SOMMER (*Zentralbl. f. Gynäk.*, April 14th, 1928, p. 942) adduces evidence that of late years, in industrial areas at any rate, haemolytic streptococci no longer play the chief part in causation of septicæmic conditions following childbirth or abortion. His material comprises 58 cases of normal birth or premature birth and 186 cases of septic abortion, of which nearly all were artificially induced. The deaths numbered 44 and 164 respectively in the two groups. A haemolytic *Staphylococcus aureus* was found in the blood in 71 cases, with 86 per cent. mortality; the next place was shared by a haemolytic streptococcus and the anaerobic *Streptococcus putridus*, each with 46 cases and 81 per cent. mortality. There were staphylococcal blood cultures in 42 cases, with 89 per cent. mortality. Further analysis showed staphylococcal septicaemia to be much more frequent in the cases of infected abortions, which appear to be induced most usually by irregular practitioners who undertake in addition a considerable amount of unqualified treatment of skin disease. The figures are from a Berlin clinic.

#### 503. The "R" and "S" Forms of Pneumococcus.

M. H. DAWSON (*Journ. Exper. Med.*, April 1st, 1928, p. 577) mentions that, following the discovery by Arkwright of two variants of the same bacterial species, "R" (rough) and "S" (smooth), Griffith was the first to recognize two corresponding variants of the pneumococcus. The distinguishing features of these are as follows. "S" forms are virulent, produce the specific soluble substance upon which type specificity depends, and form colonies which have a smooth surface when examined by reflected light. "R" forms are avirulent, do not produce the specific soluble substance, and form colonies which have a rough surface. The question of their interchangeability has considerable significance in the problem of epidemiology and in the interpretation of bacterial mutation. Dawson has made a series of experiments on the interconvertibility of the two forms, and especially on the reversion from "R" to "S." He has previously shown that virulence and type specificity could be restored to "R" forms by growth in anti-"R" sera, and cites Soule's findings that by the incorporation of "S" or "R" immune sera in fluid media "R" may be obtained from "S" and "S" from "R" forms respectively. In these experiments, made *in vitro* by growth in anti-"R" sera as well as *in vivo* by animal passages, both mass and single cell cultures of Types I, II, and III pneumococci were employed. Dawson found that "R" pneumococci may revert in all respects to the "S" type, and that in all instances in which reversion occurred the "R" forms invariably reverted to the same specific type from which they were originally derived. Reversion from "R" to "S" was always accompanied by the acquisition of maximal virulence.

#### 504. Resistance of Tubercle Bacilli to Putrefaction.

ACCORDING TO V. M. PALMIERI (*Rif. Med.*, February 27th, 1928, p. 205) it is generally agreed that the tubercle bacillus is one of the most resistant organisms known to external agencies, such as high temperature, drying, and water, but excluding sunlight. This peculiarity is due to its waxy covering and high fat and lipid content. Observations regarding its capacity of resistance to putrefaction are both scanty and contradictory. Palmieri records the case of a man, aged 21, who was exhumed after four months' burial, his death being due to pulmonary tuberculosis, which was alleged to be the result of a wound in the chest six months previously. In spite of the advanced stage of decomposition naked-eye appearances of tuberculosis were found in the lungs, in which numerous tubercle bacilli were found by Ziehl-Neelsen's stain, as well as with Gram's and Bozzelli's methods. Animal inoculation was not employed, since the lungs had been immersed in formalin at the time of exhumation.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 505. Pulmonary Ventilation in Phthisis.

R. WILLIAMSON (*Quart. Journ. Med.*, April, 1928, p. 371) has made observations on the pulmonary ventilation, oxygen consumption, and respiratory quotient of patients suffering from pulmonary tuberculosis and of normal individuals. Experiments were performed in three groups: in the first, a series of observations were made on the same patient, who had been fasting and at rest for fourteen hours; in the second group the records were made three times during the day on the same patient, the initial readings being taken under the basal conditions present in the first group; in the third series determinations were made on healthy subjects at varying times during the day. The results of these investigations showed that the pulmonary ventilation and consumption of oxygen varied from time to time in the same patient under the same basal conditions of rest and fasting; by plotting these values against each other it was found that each was directly proportional to the other. The same direct ratio was found to hold in the second group of experiments, where the variables fluctuated with the taking of exercise or food. In the normal subject the correspondence between ventilation and oxygen consumption was less marked owing to the variability of the respiratory quotient. The author considers that for practical purposes the pulmonary ventilation is a measure of oxygen utilization, and therefore of metabolic rate, and he suggests that determination of pulmonary ventilation made under constant conditions may be a useful means of estimating the progress of a patient. With a given oxygen consumption the tuberculous patient is found to have a greater ventilation than a normal subject, and this observation is adduced to explain the fact that dyspnoea is more readily produced by work in the tuberculous than in the healthy individual.

### 506. Anginal Attacks Due to Tobacco.

E. MOSCHOWITZ (*Journ. Amer. Med. Assoc.*, March 10th, 1928, p. 733) records four illustrative cases, in persons aged from 35 to 62, in whom tobacco smoking caused anginal pains, which ceased when they no longer smoked. One of the four was a woman. They had all smoked for many years previous to the seizures. Two smoked only Turkish cigarettes, and two strong Havana cigars with occasional pipes, so that the variety of tobacco used apparently made no difference. The pain of tobacco heart differs from that of coronary or aortic disease in being more intense, of longer duration, and usually accompanied by little or no disturbance of heart function. A prominent feature is the apparent sensitization which occurs. In some cases more or less pain was caused by merely puffing a cigarette or sitting in an atmosphere of tobacco smoke. Moschowitz describes two varieties of tobacco heart: (1) those in which evidence of cardiac injury is not present, and (2) those in which the signs are suggestive of the intraventricular conduction disturbance associated with coronary or aortic disease. In the latter tobacco is probably the exciting cause of the anginal pain. Treatment consists in complete withdrawal of tobacco, as mere limitation of its use is not enough. The pains do not cease immediately after withdrawal, but they continue for many weeks or even months. Although the mechanism of tobacco angina is not definitely known, the most probable explanation is that it is due to the constrictive action of tobacco on the blood vessels.

### 507. Encephalitis in Measles.

THE rarity of nervous complications in the course of measles (Bouheim in 5,910 cases only noted their presence in 0.4 per cent.) induces D. BLASI (*La Pediatria*, April 1st, 1928, p. 362) to record a case in a child aged 3. Four days after the appearance of a typical measles rash generalized convulsions developed; they were rather more marked on the left side, and between the attacks the child was in a stuporose state, with occasional cephalic cry. She refused food for two days, but had no vomiting, and there were no pulmonary or cardiac changes. There was slight strabismus and neck rigidity. The knee-jerks were exaggerated. Kernig's sign was absent, and lumbar puncture gave no evidence of meningitis. The symptoms lasted about six days and then slowly disappeared; after a few weeks the child completely recovered. The author believes the encephalitis in this case was probably due to the measles toxin.

### 508. Capillary Dilatation in Deep-seated Inflammation.

A. PARAVICINI (*Rev. del Instituto Medico "Sucre,"* January-February, 1928, p. 49) has observed that many patients with deep-seated inflammatory processes present illiform subepidermic striae of a bright red colour and of a permanent character, localized on the skin of the trunk, especially that of the supraspinous fossae at the site corresponding to the pulmonary apices, the extent of this striation varying with the severity of the subjacent lesion. The striae may also be found on distinct parts of the shoulder and breast, corresponding with lesions in the mediastinum, pericardium, or pleura. They resemble those met with on the nostrils of alcoholic subjects, but differ from them in their greater docility. In all the cases in which the author observed the sign it was constantly associated with deep-seated lesions, usually of a tuberculous nature. The condition is thought to be a dilatation of the superficial cutaneous capillaries, which is at first transient and subsequently becomes permanent. The only other changes in the skin observed are dryness, slight increase of thickness, occasional branny desquamation, and adhesions. Most of the author's observations were made in mining centres, where the sign was frequently met with, especially among subjects of pneumoconiosis and dry pleurisy.

### 509. Diagnosis of Glandular Fever.

L. D. CADY (*Amer. Journ. Med. Sci.*, April, 1928, p. 527) discusses the diagnosis of sporadic infectious mononucleosis (glandular fever), and reports nine cases. He concludes that the diagnosis from such conditions as syphilis, tuberculosis, and Hodgkin's disease can only be established by careful study of the differential white cell count in association with the clinical features. The clinical symptoms may persist for a few months, but the abnormal blood picture continues for months or years after the initial attack. Patients may be affected in the fourth or fifth decades, as well as during childhood and early adult life.

### 510. Treatment of Laryngeal Diphtheria.

E. S. PLATOU and C. A. STEWART (*Minnesota Med.*, March, 1928, p. 170) have found two measures of value in the treatment of laryngeal diphtheria. The first of these is laryngeal suction for removing laryngeal membrane. Through a laryngoscope a plain semi-soft or metal catheter is introduced, the distal part of which is attached to a suction machine. Over a two-year period the incidence of intubation was reduced approximately one-half by this method, which is comparatively simple after practice with the laryngoscope. The second measure is intraperitoneal injection of antitoxin. Tests showed that this method was second only to the intravenous, and that sufficient antitoxin was present in the blood one hour after intraperitoneal injection to neutralize all the circulating toxin in the very worst case of diphtheria.

## Surgery.

### 511. Embolotomy.

U. BANI (*Il Policlinico, Sez. Chir.*, March 15th, 1928, p. 117) reports the case of a woman, aged 39, admitted into hospital with a history of sudden pain in the right leg, followed by coldness and deadness of the limb, and gangrene, evidently due to an embolus in the femoral artery. The leg was amputated in the middle third of the thigh. A week later the patient was seized with a similar sudden attack of pain in the left leg, and there was evidence of an embolus in the left femoral artery. The leg was cold and insensible; the reflexes were absent, and no pulse could be felt below Scarpa's triangle. In spite of her grave general condition the clot in the femoral artery was removed about six hours after the onset of the symptoms. Local anaesthesia was used and an embolus about 4 cm. long was extracted from the artery. The arterial wound was sewn up with catgut without involving the intima; silk threads were left on the artery and were brought out of the external wound in case secondary haemorrhage should occur. The immediate result of the operation was excellent, the leg became warm, sensation returned, and pulsation could be felt in the arteries. The leg continued to do well for the next seventeen days, when, after sudden emotion, the heart, which was affected with advanced mitral stenosis and fibrillation, failed, and death occurred from embolism. No necropsy was allowed.

**512. Treatment of Suppurative Osteomyelitis.**

M. SAIDMAN (*Zentralbl. f. Chir.*, April 7th, 1928, p. 844) recommends irrigation of the medullary canal in all cases of acute or subacute osteomyelitis of long bones. After opening the medullary canal with a small trephine, within a short distance of the upper and lower epiphyses, he removes the marrow through these openings by means of a curette or spoon. The medullary cavity is then irrigated with dilute methylene blue solution or other antiseptic by means of a syringe and cannula, the latter having a lateral orifice. In the case of very long bones, such as the femur, tibia, and humerus, it is sometimes advisable to trephine the diaphysis at three or even four equidistant points; it may also be necessary to introduce a curved sound through the trephine openings before the medullary canal can be irrigated thoroughly. Saidman describes the case of a man, aged 53, who had a typical attack of subacute osteomyelitis in the upper half of the left tibia. The operation was performed under local anaesthesia. Two small incisions were made at the upper and lower borders of the painful area. Through these the medullary canal was opened by means of a small trephine, the outlet being made larger than the inlet, and the marrow in the vicinity of the trephine openings was removed with a spoon. Pus flowed from both orifices. The wounds were lightly plugged and the limb was fixed in a Volkmann's splint in the position of rest. The temperature rose at first and then fell slightly, otherwise there was but little change in the clinical condition. Two days later the medullary canal was irrigated with a weak antiseptic solution under very low pressure. From the exit orifice a mixture of the solution, pus, and masses of marrow containing large drops of fat escaped, and the irrigation was continued until the solution was clear. The procedure was performed six times; only after the first treatment was there a rise of temperature and increased pain in the inflamed area, which necessitated the administration of a hypodermic injection of morphine. On the next day the patient was free from pain and slept soundly. The rapid improvement that followed the first irrigation was evidently due to the treatment. Saidman claims that this treatment is scientific, and so simple that it can be performed under local anaesthesia.

**513. Surgery of the Sympathetic Nervous System.**

G. PIERI (*Arch. Ital. di Chir.*, February, 1928, p. 487) publishes a series of cases illustrating the effect of section of the sympathetic nerves in conditions where pain is the predominant symptom, and where after abdominal section no sufficient cause is found to explain the symptoms. He reports three cases of gastralgia which could not be explained by the ordinary suppositions, where ramisection caused complete cessation of the pain. Three cases of persistent pain in the right iliac fossa not apparently due to the appendix or caecum were also relieved by ramisection. In these cases he also removes the appendix as a prophylactic measure. The next three cases refer to biliary pseudo-lithiasis, occurring in young subjects suffering from pain in the right hypochondrium especially over the gall-bladder, and radiating to the back without fever or jaundice. One case of doubtful slight pancreatitis was relieved of pain by ramisection. The author also reports cases of renal, vesical, testicular, or pelvic pain treated similarly with success. He only resorts to this symptomatic treatment after excluding any removable cause. As to the duration of the cure, none of the cases are very old—the oldest goes back only two years—but in every case the relief has been maintained to date. Pieri adds that when operating on the dorsal roots care must be taken to avoid injuring the plexus, and in every case the nerve trunks must be disturbed as little as possible. Altogether the author has performed thirty-one ramisections, with one death from broncho-pneumonia.

**514. Prevention of Post-operative Bleeding in Haemorrhoids.**

J. A. WESSLER (*Med. Journ. and Record*, March 21st, 1928, p. 310) considers quinine, urea hydrochloride, and conglutin to be an ideal combination for the prevention of post-operative haemorrhage in haemorrhoidectomy. He prefers local to general anaesthesia, using a 1 per cent. solution of quinine and urea hydrochloride with the addition of 3 per cent. conglutin, a combination which afforded a nearly bloodless field during operation in fifty cases without any post-operative bleeding. After dilatation of the sphincters under a 1 per cent. solution of novocain the most dependent haemorrhoid is injected with the solution from base to apex to the point of distension and blanching. After it has been drawn down the skin and pile tissue are divided at the mucocutaneous junction and a No. 30 linen thread is passed round the pedicle, the entire haemorrhoid being tied and cut off, leaving sufficient stump to prevent slipping of the ligature. Each individual haemorrhoid is similarly treated. The

advantages claimed are that the quinine and urea hydrochloride produce a prolonged anaesthetic effect, while the conglutin prevents secondary haemorrhage and provides a nearly bloodless field. Wessler advocates conglutin as being a solution of thrombokinase isolated from blood platelets; it is free from protein and there is no danger of anaphylactic shock. It is a stable preparation which remains uniform in potency; if necessary, the ampoules can be sterilized by boiling, without affecting the coagulating qualities.

**Therapeutics.****515. Treatment of Syphilis Associated with Tuberculosis.**

R. MARCLAND (*Bull. et Mém. Soc. Méd. Hôp. de Paris*, March 29th, 1928, p. 548) illustrates the harmful influence of novarsenobenzol on tuberculous syphilitic patients by describing two cases in which the first few injections were followed by uncontrollable activity in previously quiescent lesions. Arsenical compounds as a whole have, during the last fifteen years or so, fallen into disuse in pulmonary tuberculosis on account of the risk of aggravation of the disease. Such activation is brought about by the pulmonary congestion which follows the administration of arsenite, and this drug is therefore specially contraindicated when there is fever, haemoptysis, or progressive loss of weight. Considerable elevations of temperature in febrile tuberculous patients have been shown to follow five or six injections of cacodylate of soda. Marcland remarks that syphilis and tuberculosis are such common diseases that they must frequently coexist, and it is therefore important to make a thorough search for a tuberculous lesion whenever a febrile reaction or a loss of weight occurs during treatment with novarsenobenzol. Patients suffering from both diseases should not be treated with this drug unless the temperature and physical signs are carefully watched so that the administration may be immediately stopped should signs of tuberculous activity appear. If withdrawal of arsenic becomes necessary treatment should be continued with bismuth and mercury. These drugs are well tolerated by tuberculous patients, and although cure of the syphilitic condition may be delayed, it may ultimately be effected. On the other hand, it may be difficult or even impossible to arrest a pulmonary tuberculous lesion which has been lit up by the ill-advised and uncontrolled use of novarsenobenzol.

**516. The Treatment of Bronchiectasis.**

ACCORDING TO R. STRISOWER (*Wien. Min. Woch.*, April 5th, 1928, p. 495) the three most important indications to prevent the extension of bronchiectasis are to decrease the expectoration, to assist in its expulsion, and to prevent gangrene. One of the most important measures in diminishing the expectoration is to decrease the amount of fluid imbibed. It should amount to about 600 c.cm. per diem for three days, and on the fourth day, which may be called a "drink" day, the ordinary amount is taken. To avoid thirst a slice of orange or lemon may be given and the mouth may be washed out with soda-water. The following remedies can also be employed: atropine, turpentine, eucalyptus, menthol, quinine and camphor in solution, and eucalyptus and menthol dissolved in oil. To assist in its expulsion the expectoration should be made thinner by alkaline waters and potassium iodide. The most important means for getting rid of the expectoration is the adoption of Quinke's position and respiratory gymnastics. Adoption of the following position is often efficacious—the patient should be in the dorsal position with the pelvis raised, and should then take deep breaths. He should then bend the hips and knees and press them firmly into the abdomen. Salicylates and diathermy have also proved useful. If there are signs of gangrene neosalvarsan injections should be given; should there be no result after six or eight they must be abandoned. An operation is indicated if the sputum is excessive and purid, or if the disease progresses in spite of treatment.

**517. Ephedrine in Asthma and Hay Fever.**

R. GREEN (*Malayan Med. Journ.*, March, 1928, p. 10) records his observations upon the symptomatic treatment of asthma and hay fever with ephedrine. The hydrochloride was given orally in doses varying from 1/2 to 1 1/2 grains in ten asthma cases, while in two cases of hay fever a 3 per cent. ephedrine sulphate solution was applied locally to the nasal mucous membrane. Each asthma patient was kept under observation for from two to six hours, and in some cases the blood pressure was recorded every half-hour. Complete relief was obtained in six of the ten cases, while five developed toxic symptoms, including mental confusion, urticaria, palpitation, tremor, sweating, tachycardia, or collapse. Green thinks

that ephedrine is of much the same value in asthmatic attacks as adrenalin, but has the advantage of being given by mouth instead of by injection. In view of the toxic symptoms sometimes arising small doses should be employed until tolerance is established. When the drug was used during an attack the blood pressure was unaffected or lowered, but when given during a quiescent period the blood pressure was temporarily raised, so that it would appear to have the same contraindications as other blood-pressure-raising drugs in disorders of the cardio-vascular system. In the two cases of hay fever treated by local applications of ephedrine sulphate to the swollen nasal mucous membrane marked temporary relief for three hours was obtained; 1 gram of ephedrine hydrochloride had no effect upon the symptoms, but produced a toxic effect of faintness, palpitation, and sweating similar to that noticed in some of the asthma cases.

#### 518. Treatment of Pulmonary Tuberculosis by Sanoecrysin.

V. BRE and M. S. ANDERSEN (*Acta Tuberculosis Scandinavica*, 1927, vol. 3, Fasc. 2, p. 61) publish details of a series of 35 cases of pulmonary tuberculosis treated by sanoecrysin. Injections were made intravenously as a rule, occasionally intramuscularly, of a 5 per cent. solution, and in general the dosage was regulated according to Moellgaard's directions. Two series of injections were given, sometimes three. In the early stages of the investigation an antituberculous serum was given during the first series of injections, but later this practice was discontinued. Most of the patients after treatment with sanoecrysin were dispatched to a sanatorium. Of 12 acute cases with tubercle bacilli in their sputum 6 patients died, 4 were apparently cured (1 relapsed later), 1 remained stationary, and 1 was improved. Of 12 acute cases, and 2 chronic cases with acute exacerbations, without tubercle bacilli in their sputum, 1 patient died, 9 were apparently cured (but 2 relapsed later), 3 were probably cured (but were not examined later), and 1 was improved. Of 8 chronic cases with tubercle bacilli in their sputum 3 patients died, 1 was apparently cured, 2 were improved, and 2 remained stationary. Two patients with chronic disease but without tubercle bacilli in their sputum were apparently cured. Against these may be set 19 cases that were not treated by sanoecrysin. Seventeen of these were acute cases, or chronic cases with acute exacerbations, with tubercle bacilli in the sputum; of these, 9 patients died, 4 were improved, and 4 were worse. Of 2 acute cases without tubercle bacilli 1 patient died, the other was improved. The authors consider that these figures demonstrate the value of sanoecrysin treatment.

### Ophthalmology.

#### 519. Transmission of Arsenic to the Aqueous Humour.

A. M. YUDKIN, A. C. KRAUSE, and D. G. MORTON (*Arch. of Ophthalmol.*, March, 1928, p. 147) describe four experiments on dogs with regard to the transmission of arsenic to the aqueous humour. They found that, whereas after intravenous injection of large doses of arsenical compounds practically no arsenic could be found in the aqueous, yet if paracentesis of the anterior chamber was performed shortly before or after the intravenous injection arsenic was found in the aqueous fluid, and, further, that this presence of arsenic in the aqueous could be increased by further paracentesis. The arsenic present in the aqueous fluid after these procedures leaves the anterior chamber in a few hours. The instillation of pilocarpine and eserine helps to increase the quantity of arsenic in the aqueous. In view of their experiments the authors suggest that in cases of syphilitic affections of the eye, and in particular in cases of interstitial keratitis, paracentesis of the anterior chamber should be performed near the time of the intravenous injection of an arsenical compound, and that the paracentesis might with advantage be repeated again within a few hours, and that concurrently pilocarpine or eserine drops should be instilled into the eye.

#### 520. Keratitis Due to an Infection of Trachoma.

DURING the course of annual autumnal epidemics of acute conjunctivitis in Athens, due often to the bacillus of Weeks, B. ADAMANTIADIS (*Ann. d'Oculist.*, February, 1928, p. 119) has noticed that in certain patients, particularly infants, a latent trachoma becomes apparent during the decline of an acute conjunctivitis; the course of this acute condition was much longer in trachomatous subjects, and favoured complications of the cornea or aggravated existing ones. This ulcerative keratitis, caused by a superinfection of the trachoma by Week's bacilli, differs from other forms of keratitis in the following characteristics. The ulceration, always due to this bacillus, occurs in debilitated cases, and is limited to

the middle of the cornea on the horizontal meridian. It is in the form of a furrow, very deep in the centre and less so on the two sides, perforation always occurring in the centre. The edges appear polished, shiny, and without any greyish infiltration. The ulceration is uncomplicated by suppuration, and has a very rapid course. Two or three days after the onset of the ophthalmia the cornea is affected and speedily becomes eroded in its depth. Abundant lachrymation and intense periorbital pain accompany the corneal involvement. The prognosis is very grave, though with continuous and systematic treatment it is not hopeless. The author recommends daily cauterizations with a 1 per cent. solution of silver nitrate after careful eversion of the lid, instillations of pilocarpine or argyrol, and compress dressings. At first, owing to the lachrymation, these dressings should be changed four or five times daily, the instillations being then made, and an antiseptic ointment applied. In obstinate cases subconjunctival injections of mercury cyanide may be given combined with parotential injections of milk.

#### 521. Amaurotic Zoster.

E. ROLLET (*Journ. de Méd. de Lyon*, March 20th, 1928, p. 149), who records an illustrative case in a woman aged 70, states that in addition to the ordinary ophthalmic herpes characterized by pain, eruption, and various disturbances of the anterior segment of the eye, such as keratitis or iritis, there is a form of ophthalmic zoster in which the posterior segment is involved owing to affection of the optic nerve. The inflammation of the nerve appears to be secondary to herpetic meningitis, the existence of which is proved by lumbar puncture, which shows a distinct lymphocytosis. Whereas optic atrophy occurring in general diseases and intracranial affections is symmetrical, unilateral atrophy will often be found to be due to a previous attack of ophthalmic zoster.

#### 522. Mikulicz's Disease Treated by X Rays.

R. E. WRIGHT (*Amer. Journ. of Ophthalmol.*, December, 1927, p. 903) describes a case of this disease in which the lacrimal and submaxillary glands were involved. The swelling of the lacrimal glands was so great that corneal ulceration ensued and the lids had to be sutured. X-ray applications were given over a period of six weeks, two being given to the left eye, which was the one least involved, and six to the right eye. At the end of the six weeks the swelling of the lacrimal glands had disappeared.

### Obstetrics and Gynaecology.

#### 523. Surgical Intervention in Extrauterine Pregnancy.

H. P. BROWN, Jun. (*Annals of Surgery*, April, 1928, p. 531) records the experiences gathered from 109 cases of ectopic gestation treated at the Pennsylvania Hospital. Regarding the etiology and pathology of this condition, Robinson has stated that it is due rather to a functional disturbance of the tube than to an inflammatory and mechanical condition of the tube itself, and numerous authors have shown that the cause of rupture and haemorrhage, conditions chiefly responsible for the symptoms, are dependent not only on the distension of the tube by the growing embryo, but also on the degree of penetration of its walls and blood vessels by the foetal elements. In the present series a combination of vaginal bleeding and abdominal pain was the most frequently seen—namely, in 55 per cent. of the cases—while lower abdominal pain without haemorrhage occurred in 36 per cent. Salpingitis was noted as having been present in only 10 per cent., while a high leucocyte count was not observed frequently enough to be of diagnostic value. In no instance was the temperature on admission above 101° F. The onset of the symptoms was found to be often insidious, depending largely on the degree and rapidity of rupture of the tube or embryonic sac. The differential diagnosis between ectopic pregnancy and conditions simulating it, especially salpingitis and appendicitis, is frequently difficult. In the present cases the right side was involved in 53 per cent. and the left in 38 per cent., while on operation the tube alone was removed in 81 per cent. and both tube and ovary in 15 per cent. In two cases both tubes were excised, and in one ovarian pregnancy only the ovary. The mortality was 6.3 per cent. Brown concludes that diagnosis is difficult in atypical cases; and that much reliance cannot be placed in the menstrual history or the absence of previous pregnancies. In doubtful cases where an acute surgical emergency is not present reasonable delay is permissible in order to arrive at a correct diagnosis, but in those presenting symptoms of active bleeding immediate operation is necessary without waiting for a reaction from shock, since there is always a chance of recovery despite extensive intra-abdominal haemorrhage or shock. Where indicated an autotransfusion may be beneficial.

## 524. Treatment of Ovarian Cysts during Pregnancy.

M. BROUHA (*Bruxelles-Medical*, April 15th, 1928, p. 803) states that, while the systematic operative treatment of ovarian cysts during the first months of pregnancy is generally approved, opinions differ as to its advisability during the latter months. Despite the dangers of torsion, rupture, and suppurative of the cyst, surgical intervention, practised by certain authorities, is not recommended by Brouha owing to the risk of causing a premature accouchement and eventration due to rupture of the abdominal cicatrix; a case of this nature is cited. When the cyst lies in the abdominal cavity spontaneous natural delivery is possible, and the cyst can be treated at the end of the puerperal period. Pelvic cysts cause a mechanical obstruction, and other measures are necessary. Manipulation of the cyst into the abdomen is tedious and risky; puncture, formerly much practised, and vaginal incision of the tumour have been abandoned. Ovariectomy is the method of choice, and Brouha advocates the combining of this operation with natural delivery. When dilatation of the os is almost complete, and not before, he opens the abdomen, removes the cyst, temporarily closes the abdomen, and terminates labour per vaginam by forceps or version. Two cases treated with complete success in this manner are reported. This method is not applicable when the cyst lies intraligamentally, or when strong adhesions are present. There is also risk in cases where the foetal vitality has already suffered, as the exteriorization and luxation of the uterus may cause disturbances of the placental circulation capable of producing foetal asphyxia. These are said to be the two only contraindications, and the method possesses the immense advantage of conserving the uterine integrity, which is so advisable for future pregnancies and labours. Brouha recommends a definite closing of the abdomen only at the end of the accouchement, as then the reduced size of the uterus renders suturing much easier. Moreover, it is thus possible to verify a haemostasis of the pedicle, which is liable to be interfered with during delivery.

## 525. Antistreptococcal Serum in Treatment of Puerperal Septicaemia.

C. BERNARD (*Gynéc. et Obstét.*, March, 1928, p. 216) reviews the results given by treatment by antistreptococcal serum in puerperal septicaemia. Thirty-five cases were treated; in all the diagnosis was confirmed by blood culture, bacteriological examination of pus from metastatic abscesses, or necropsy. Streptococci were found in the blood in eighteen cases. The proportion of cures was 37.1 per cent.; if the cases are deducted in which death occurred within a few hours of the serum being injected, as well as those in which the pathological agent was other than a streptococcus, the cures numbered 47.3 per cent. The doses advocated are high: from 80 to 100 c.cm. In two injections during the first day and on succeeding days from 60 to 80 c.cm. Two or three days are required in which to judge of the efficacy of the treatment. The conclusion is drawn that the serum may act (1) in about 20 per cent. of cases, rapidly and perhaps specifically, the temperature falling and the general condition improving as from introduction of antibodies is appropriate to the infecting agent; (2) more slowly and indirectly, its efficacy being non-specific and equal or inferior to that of colloidal metallic preparations given intravenously.

## Pathology.

## 526. The Action of Ergotamine on the Autonomic System.

M. GOLDMAN (*Arch. des Mal. du Cœur*, April, 1928, p. 204) has observed the effect of ergotamine, the principal active constituent of ergot, on normal individuals and on those suffering from various diseases. This substance was injected into and under the skin and intravenously in doses of 0.25 mg. upwards of the tartrate. A diminution of pulse rate varying between 6 and 60 beats a minute was found; this was due either to excitation of the cardio-inhibitory mechanism or to predominance of the latter as a result of paralysis of the sympathetic terminations. When atropine had been previously administered the reduction of the pulse rate was even more marked. In relation to adrenaline it was found that this drug would abolish the ergotamine effect, whereas ergotamine did not influence the effect of adrenaline. The fact that ergotamine has a variable effect depending upon the bodily state at the time of administration was shown by the accelerating influence on the pulse rate in a patient suffering from hyperthyroidism. The effect of this substance on the blood pressure was always to increase the diastolic pressure. Generally the pulse pressure rose, but in a few cases there was a fall, so that the systolic pressure dropped below the

original level. This alteration of diastolic pressure by ergotamine is comparable with the effect of adrenaline, but the change is more prolonged. It is concluded from these investigations that ergotamine excites the sympathetic innervation and the muscles of the peripheral vessels, while in the heart it activates the parasympathetic and perhaps paralyzes the sympathetic. The sympathetic supply to the stomach is stimulated so that secretion and motility are diminished. The therapeutic indications for ergotamine are the following: circulatory disorders with a tendency to tachycardia, whether paroxysmal, toxic, or glandular; cases of transient or permanent hypotension, especially in circulatory failure; and digestive troubles associated with excessive secretion and motility.

## 527. Infectious Necrotic Hepatitis in Australian Sheep.

A. W. TURNER (*Ann. de l'Inst. Pasteur*, February, 1928, p. 211) has previously submitted evidence to show that the black disease (infectious necrotic hepatitis) of Australian sheep is essentially a localized infection of the liver due to *Cl. oedematis*. He now gives an account of the experimental reproduction of the disease in animals, and the preparation of a protective vaccine. By cultivating the organism for several generations in a glucose nitrate agar medium he obtained a type which was highly virulent but only slightly toxic to guinea-pigs. Injected in a dose of 0.25 c.cm. it gave rise to local oedema, and to a pleural and peritoneal effusion; but instead of the organisms being confined to the local lesion they were found in the serous effusions, in the viscera, and in the blood. In one out of ten guinea-pigs injected with this dose necrotic areas were found in the liver containing large Gram-positive bacilli which proved to be *Cl. oedematis*. Similar areas of necrosis in the liver were found in a sheep injected with the bacillus. Experiments seem to indicate, however, that the appearance of these necrotic areas, both in guinea-pigs and in sheep, is the exception rather than the rule. Vaccination experiments were attempted in both animals, but with rather ambiguous results. A formalized whole culture of *Cl. oedematis* injected on one, two, or three occasions into guinea-pigs gave rise to no definite immunity. In sheep the results appeared to be more hopeful, but unfortunately so few animals were available for use as controls that the interpretation of the experiments was difficult. The author thinks, however, that animals can be protected with a suitable vaccine, but that an experiment in the field on a large scale is necessary before the value of prophylactic vaccination can be ascertained.

## 528. The Mesenteric Glands and Fat Absorption.

C. CASSANO (*Il Policlinico*, Sez. Med., February 1st, 1928, p. 93) reports a histological investigation of the function of the mesenteric glands in dogs during the digestion of fats. The stains used for the microscopic sections were Sudan III and haematoxylin, and the method of Ciaccio for lipoids. Cassano found that the fatty substances in the mesenteric glands did not exist only as neutral fats, but also as soaps and fatty acids. Two hours after the ingestion of a fat-containing meal the glands showed conspicuous activity in building up the large fat molecules at the expense of the soaps and other lipoids. After twelve hours' digestion the neutral fats prevailed in greater quantity than the soaps. At this period also he noted deposits of neutral fats inside the blood vessels. It thus appeared that there was a gradual passage of these fats into the blood circulation, this being contrary to the opinion formerly held that the fats pass wholly by the receptaculum chyli into the thoracic duct. From twenty-four to forty-eight hours after the last meal there was always to be seen a large quantity of fat in the glands, indicating that they acted as a storehouse to economize the fats. During protracted fasting (seven to fifteen days) the mesenteric glands still conserved part of the deposited fats, and at the same time it was noted that a certain amount of separation had occurred, liberating the fatty acids and augmenting the soaps.

## 529. Bacteriological Examination of Rheumatic Nodes.

B. LE BOURDELLES (*C. R. Soc. de Biologie*, March 9th, 1928, p. 691) examined bacteriologically two small subcutaneous nodes removed during life from the scalp of a young man suffering from cardiac rheumatism. The nodes, which were taken out under strict aseptic precautions, were dropped, the one into glucose peptone broth, the other into a modified Noguchi medium. On the fourth day a streptococcus developed in the glucose broth, and on the tenth day in the Noguchi medium. Subcultures made from these primary cultures remained sterile. The organism did not haemolyse the patient's blood. The author considers this finding of a streptococcus as of interest in relation to the etiology of acute rheumatism.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 530. The Phrenico-Pupillary Syndrome in Pleuro-pulmonary Affections.

E. SERGENT and P. GEORGE (*Presse Méd.*, April 28th, 1928, p. 529) conclude that in addition to the information given by the direct investigation of the respiratory apparatus (clinical and radiological examinations) the indirect signs of localization based on anatomical and physiological considerations are to be remembered, since they can in many cases provide diagnostic help of great value. Among the most valuable of these indirect signs are the changes in the irido-dilator and phrenic nerves. These signs may exist singly or in association with each other, producing a phrenico-pupillary syndrome of variable type. There may thus occur a spasmodic mydriasis, or a paralytic myosis, or the syndrome of Claude Bernard-Horner, associated with phrenic paralysis, and completed by other signs of the mediastinal series—such as, for example, paralysis of the recurrent laryngeal nerve. The authors state that the phrenico-pupillary syndrome, which is observable in all pleuro-pulmonary affections, but principally in tuberculosis, acquires in many cases a diagnostic value where the physical signs are indistinct or still latent. It is always serviceable in making more precise the exact topography and knowledge of observed or suspected lesions. A summary of two case reports exemplifying the phrenico-pupillary syndrome, illustrated by radiograms, is given.

### 531. The Heart in Hypertension.

G. FAHR (*Amer. Jour. Med. Sci.*, April, 1928, p. 453) believes that, though the general length of life has increased during the last century, yet the adult who survives to-day until the age of 45 cannot expect to live much longer than his eighteenth century ancestors. He adds that the greatest obstacle to longevity is hyperplasia, by this term being meant a condition of high blood pressure not associated with nephritis. Heart failure associated with high blood pressure is the most common form of cardiac impairment and the most important result of high blood pressure continued for many years. Of approximately 140,000 annual deaths in the United States from the consequences of hypertension, about one-half were due to cardiac failure. Fahr discusses this condition and describes four well-followed cases. The most characteristic physical sign of the heart in hypertension is left ventricular dilatation, which causes an increase in its weight. The symptoms develop about twelve to fifteen years after the onset of hypertension if only a very moderate coronary arterio-sclerosis is present and no other complication has meanwhile occurred. The symptoms do not differ essentially from those found in heart failure due to other types of cardiac impairment, though pulsus alternans is more frequently found in hypertensive hearts. The blood pressure may remain high even to within twenty-four hours of death, though it may fall, especially if arricular fibrillation or marked coronary sclerosis be present. Treatment should be directed towards lowering the blood pressure and reducing the physical activities of the patient, thus lessening the work of the exhausted heart muscle. Digitalis, diuretics, and sedatives have the same indications as in other forms of heart disease with failure, and long-continued rest in bed is probably the most effective measure in treatment. Venesection helps in emergencies where the venous pressure has risen above 20 cm. of water.

### 532. Exophthalmic Goitre and Lead Ionization.

J. MILLER, P. M. MACDONNELL, and A. F. G. CADENHEAD (*Canadian Med. Assoc. Journ.*, April, 1928, p. 400) record a case of exophthalmic goitre complicated with toxic adenoma and treated by lead ionization. A woman, aged 46, was admitted to hospital with symptoms of advanced exophthalmic goitre and symmetrical enlargement of the thyroid gland, which for the previous year had rendered swallowing increasingly difficult. Failure in treatment led to the supposition that the enlargement was possibly malignant. Lead ionization was performed twice a week for five months; the electrolyte was lead nitrate, and each administration lasted for fifteen to twenty minutes, representing a dose of about 10 mg. of lead at each treatment. Marked improvement in all symptoms resulted, though surgical intervention was

contraindicated on account of the cardiac condition. The patient left hospital much better, but returned two months later very much worse, and died in spite of active treatment. Post-mortem examination revealed an encapsulated foetal adenoma of the thyroid gland buried in a colloid goitre which showed marked degenerative changes. On chemical analysis the lead content of the thyroid proper approximated 6 to 8 mg., but there was no trace of lead in the foetal adenoma. The authors conclude that the case was primarily one of exophthalmic goitre, and that the degenerative changes and relatively large lead content found after death pointed to the lead ionization being an important factor in the diminution in the size of the gland and in the improvement in symptoms. The rapidly with which the patient became worse is attributed mainly to the growth of the toxic adenoma developing in the last few months; this was probably not present during the time the lead ionization was being performed, since lead was absent from the growth. The fact that lead ionization appears to cause degenerative changes in the cells of a parenchymatous goitre, with marked diminution in its size and general improvement in health, suggests the practical utility of such treatment, followed, as soon as the swelling has been reduced, by surgical intervention in those cases in which there is no cardiac or other contraindication.

### 533. Diabetic Psychoses.

H. J. SCHIM VAN DER LOEFF and J. A. J. BARNHOORN (*Nederl. Tijdschr. v. Geneesk.*, March 24th, 1928, p. 1465) state that diabetic psychoses—that is, psychoses causally connected with diabetes mellitus—occupy only a small place in the group of symptomatic psychoses and are rarely observed. The authors record four illustrative cases in women, their conclusions being as follows. (1) Diabetic psychoses may appear in the form of dementia, hallucinations, and delirium. (2) The term "diabetic psychosis" should be used when symptoms develop in a diabetic patient in association with an aggravation of the primary illness and disappear as the diabetes improves or coma ensues. (3) The development of paranoid or manic-depressive symptoms must be regarded as mere coincidences which originated before the attack of diabetes. (4) In spite of the rarity of diabetic psychoses the possibility of their occurrence should always be considered in cases of mental disorder, as their timely recognition and antidiabetic treatment may be of great benefit.

## Surgery.

### 534. Treatment of Acute Cholecystitis.

H. O. BRUGGEMAN (*Annals of Surgery*, March, 1928, p. 423) compares acute cholecystitis with acute salpingitis as being rarely fatal if treated conservatively. It is not comparable with acute appendicitis, which is a lethal disease, since it so frequently results in diffuse peritonitis. Acute cholecystitis rarely causes widespread peritonitis because when the gall-bladder becomes inflamed it is soon walled off from the peritoneal cavity. The author thinks that an operation during the acute stage of cholecystitis is seldom required and should be avoided until the active inflammation has subsided. Rest, morphine, and fluids suffice in most instances to limit the inflammatory process. The gravest danger in conservative treatment is a mistaken diagnosis. There is a wide difference of opinion about the indications for operation in these cases and as to the best procedure to adopt. Bruggeman thinks that cholecystectomy is usually preferable, though cholecystostomy may be wiser as the more simple operation. He insists that in acute cholecystitis an operation is very rarely indicated. In mild cases any form of treatment will make but little difference to the result.

### 535. Intussusception of Meckel's Diverticulum.

J. HOLST (*Norsk Mag. f. Lægevid.*, March, 1928, p. 279) reports the case of a boy, aged 12, who was admitted to hospital with the diagnosis of acute appendicitis. He had been ill for twenty-six hours with acute abdominal symptoms. On laparotomy an intussusception of the ileum 20 cm. in length was seen and was found to be due to Meckel's diverticulum, which had become invaginated into the lumen of the small intestine and had given rise to intussusception in a similar manner to

that caused by a pedunculated polypus. The blind end of the diverticulum showed a polypus the size of a pea. The intussusception was reduced and the diverticulum was resected; recovery followed.

### 536. Treatment of Varicose Veins by Injections.

IN view of the hither and poor results attending the use of elastic stockings and bandages in the treatment of varicose veins, W. WOLF (*Med. Journ. and Record*, April 18th, 1928, p. 416) concludes that the only satisfactory local method is to obliterate these veins, thereby preventing their rupture or the production of varicose ulcers. Surgical extirpation of the affected vessel or the tying of the trunk vein at a higher point is not recommended because the circulation is seriously interrupted, the patient is laid up for some time, and the leg never looks or feels normal afterwards. Another method is to inject the vein with a solution which is not injurious, does not cause coagulation of the blood with the consequent danger of embolism, and which will produce such inflammation of the vessel walls as will cause obliteration of its lumen. Substances such as iodine or sodium bicarbonate should not be employed owing to the coagulation and violent inflammation they cause. Those, in the order of their importance, which may be used are: a 60 per cent. dextrose solution; a 20 to 25 per cent. sodium chloride solution containing a small amount of local anaesthetic; a 1 to 3 per cent. mercuric bichloride solution; 5 to 20 per cent. phenol in glycerin and water; 5 to 10 per cent. quinine orcin hydrochloride; and a 20 per cent. salicylate solution with a small amount of local anaesthetic added to prevent painful cramping of the veins. Wolf describes his method of injection, and emphasizes that a particular and carefully executed technique is of greater importance than the substance used. A reaction usually occurs in from twelve to seventy-two hours, and consists in a swelling and tenderness around the operation area, but this is rarely severe enough to incapacitate the patient or to require treatment. With correct technique no untoward results or failures need occur, the patient is not laid up in bed, the symptoms commonly associated with varicose veins (eczema, ulcer, cold feet, and a feeling of heaviness in the legs) are rapidly relieved and disappear, and the desired obliteration of the vein is produced.

### 537. Fractures of the Acetabulum.

E. L. ELIASON and V. W. M. WRIGHT (*Surg., Gynecol. and Obstet.*, April, 1928, p. 539) define three groups of central dislocation fractures of the acetabulum: (1) fractures of the rim; (2) radiating, including fractures and epiphyseal separation of the floor; and (3) penetrating, with or without intrapelvic displacement of the femoral head. Over 50 per cent. of the cases are complicated by other pelvic fractures with varying manifestations from associated pelvic and abdominal injuries. Diagnosis of the nature and degree rests principally upon x-ray examination, but symptomatically there may be flattening of the trochanter, shortening, flexion, abduction, and external rotation. Obturator pain from injury to or pressure upon the nerve, crepitus, and symptoms arising from injury to blood vessels and bladder may also be present, while there is always tenderness on lateral pressure over the trochanter. All movements of the thigh are restricted, but patients have been able to walk immediately after the injury, which may have been unrecognized at the time. Lesions of the sciatic nerve may result in varying degrees of paralysis and pain. Direct violence over the great trochanter is the cause in the majority of cases (60 per cent. of the authors' cases and 97.5 per cent. of those reported in the literature). Associated complications require prompt treatment, and reduction is best performed by closed methods under ether anaesthesia with complete muscular relaxation, open operation being contraindicated. Reduction should be maintained by the application of a plaster-spica with the thigh in abduction, slight flexion, and external rotation.

### 538. Treatment of Gastric and Duodenal Ulcer.

J. L. DECOURCY (*Annals of Surgery*, April, 1928, p. 556) remarks that the treatment of gastric or duodenal ulcer varies according to the pathological condition found in each individual case. While focal infection is a definite etiological factor in these ulcers, daily misuse of the stomach function is also an important cause. The lesions always coexist with a gastric hyperacidity, and treatment is based on the alleviation of this symptom and the protection of the ulcer from its ill effects. DeCourcy classifies peptic ulcers as follows: ulcer of the mucosa, of the submucosa, indurated ulcer, and delaminating ulcer with or without induration. Ulcers extending no deeper than the mucosa usually yield to proper medical treatment, and, especially in patients under 30, this should be given a thorough trial before an operation is advised. For submucosal ulcers DeCourcy advocates, particularly in cases under 40, gastro-enterostomy with canterization of the ulcer or ulcers from within the stomach. Careful

search should be made for multiple ulcers, since it is possible that gastro-jejunal ulcers following posterior gastro-enterostomy are due to contact infection from the original ulcer, as in the "kissing" ulcers of Meynihan. For indurated ulcers, in particular in patients over the age of 40, partial gastrectomy should be performed in preference to gastro-enterostomy. The author advises this drastic measure as a prophylaxis against subsequent carcinoma, and, while granting the high mortality in such operations, believes that with improved technique their safety will be much increased, as has occurred in cholecystectomy and thyroidectomy, operations formerly very dangerous. He emphasizes the need of a careful closure of the duodenum, since this is an important factor in the mortality.

### 539.

#### Acute Appendicitis.

E. P. QUAIN and R. H. WALDSCHMIDT (*Arch. of Surg.*, April, 1928, p. 858) record a study of 1,000 consecutive cases operated on for acute appendicitis. A trial of the treatment recommended by Ochsner was abandoned after several unfortunate experiences, and all patients are now operated on without preliminary treatment. The authors believe that the best chance of recovery lies in immediate operation with efficient drainage of the peritonium. The split muscle incision was employed, and can be enlarged by cutting across the linea semilunaris. Post-operative hernia was found in 1.5 per cent. of cases. In cases of intestinal distension a small rubber tube is passed into the caecum through the stump of the appendix; these fistulas soon heal and are serviceable while they last. Where there is widespread peritonitis and great distension enterostomy should be performed at once through a separate incision. The majority of the patients soon had received a purgative soon after the onset of the disease; the authors think that this practice is strongly to be condemned in cases of acute appendicitis. The mortality in the 1,000 recorded cases was 2.5 per cent.

## Therapeutics.

### 540.

#### Antitoxic Action of Yeast Extract.

G. LEMOINE (*Bull. Soc. de Thér.*, March 14th, 1921, p. 90) suggests an ethereal extract of yeast for the treatment of infectious diseases. In his previous investigations he had employed pyocyanase, which is an alcoholic extract of dry cultures of *B. pyocyanus*, and then an ethereal extract of these cultures. With the last product he had obtained excellent results in the treatment of diseases due to streptococci. The work of E. Gérard and the more recent investigations of Benoit, which had shown the resemblance between the extracts of cultures and yeast extracts, induced Lemoine to employ the latter in the treatment of infectious diseases, such as streptococcal infections, erysipelas, puerperal fever, scarlatina, and septicæmia, as well as in other affections in which the streptococcus is an associated organism. In scarlet fever in particular and in measles the results were remarkably striking, the fever and constitutional disturbance subsiding in less than forty-eight hours. The yeast extract employed by Lemoine is essentially composed of lipoids, ergosterin, and undetermined nitrogenous compounds, and it is to the combination of these products that the author attributes the good results obtained.

### 541.

#### Pituitrin in the Treatment of Migraine.

K. ZEINER-HENRIKSEN (*Tidsskrift f. d. Norske Lægeforening*, March 15th, and April 1st, 1928, pp. 250 and 312) has treated forty-two cases of migraine with pituitrin during a period of two years and nine months, and has achieved prolonged improvement in twenty cases. An intramuscular injection of 0.5 c.c.m. was given once a week. In one case, that of a woman who had been subject to regular attacks of migraine since she was 7 years old, the treatment was started at the age of 23. After three injections no further attacks occurred. She received altogether twelve injections, and was free from attacks during an observation period of more than a year. Many of the patients complained of feeling very tired during the treatment, but they were still able to attend to their daily routine of duties. Discussing the rationale of this treatment, the author suggests that it may break a vicious circle, the existence of which depends on faulty functioning of the pituitary body, which at times does not produce an adequate secretion on account of some psychic disturbance or other cause. In this connexion it is pointed out that, of all the theories put forward to account for the genesis of migraine, the most plausible is that which Quincke advanced, and which depends on the assumption that an acute serous hydrocephalus develops on certain occasions. Whatever the explanation may be of the beneficial action of pituitrin, the author holds that it is more effective than other symptomatic remedies, even including luminal.

## 542. Oxygen Therapy.

J. H. EVANS (*Med. Journ. and Record*, April 4th, 1928, p. 349) suggests that anaesthesia and inhalation therapy should be regarded as combined specialties, since the latter is the natural outgrowth of the former. While inhalation therapy may eventually include the administration of other gases or combinations of gases, Evans discusses the use of oxygen only, mainly from his experience in fourteen cases of pneumonia in which from 60 to 100 per cent. oxygen was given continuously for periods of four to fifteen days. In no instance did such high concentrations act as an irritant or produce any harmful results, because pneumonia patients require more than the usual amount of oxygen in the inhaled air to bring the blood oxygen up to normal, and even a slight lack of oxygen for several days is serious, since the harmful effects of anaemia are considerable. To be effective it should be commenced early and in sufficiently high concentrations to abolish any deficiency in the arterial blood. In anaemia of the intestinal tract causing distension and suspending the digestive processes oxygen administration in high concentrations by removing the anaemia improves the prognosis. The cases show that a continuous 60 to 100 per cent. oxygen administration can be safely given over a period of several days to abolish cyanosis, and in the absence of cyanosis pure oxygen, administered for twenty minutes every hour, apparently exerts a therapeutic action. Its beneficial use is indicated in various other diseases—such as asthma, bronchitis, arthritis, burns, and cardiac cases. Evans points out that while its administration to relieve anaemia is logical, its application to diseases in which the blood oxygen is normal is illogical unless they are caused by an anaerobe which might be combated by oxygen therapy.

## 543. Liver Extract in Pernicious Anaemia.

L. LAQUEUR and A. P. W. MÜNCH (*Nederl. Tijdschr. v. Geneesk.*, April 7th, 1928, p. 1664) record their observations on fourteen cases of pernicious anaemia treated with liver extract. All the patients improved, some within a week, and the majority within a month. This was particularly noticeable in the severe cases, in most of which there had previously been relapses. At first a syrupy extract was used, and later a powder. The doses consisted of 300 grams of fresh liver daily, in some cases 400 to 500 grams. The treatment was continued for four weeks. The authors remark that their cases were not very numerous, and add that even in England, where the treatment was used before it was introduced into Holland, only about thirty-two cases have been recorded in which this treatment had been tried, the results being favourable in all except two.

## Disease in Childhood.

## 544. Angina Pectoris in Children.

E. J. STOLKIND (*Brit. Journ. Child. Dis.*, January-March, 1928, p. 1) records four personal cases and has collected twenty-five examples from the literature of angina pectoris in children aged from 7 to 14 years. After a historical note in which he vindicates Heberden's priority over Rougnou, he describes the symptoms, etiology, and pathology, which he maintains are the same in children as in adults. He is of opinion that the attack of angina is brought about by a combination of factors—namely, the chemical and toxic substances circulating in the blood, the state of the nervous system, especially the autonomic system, and the condition of the heart and aorta.

## 545. Cerebro-spinal Fever in Infancy and Early Childhood.

S. MCLEAN and J. P. CAFFEY (*Amer. Journ. Dis. Child.*, March, 1928, p. 357) record their observations on 136 cases of endemic meningococcus meningitis in patients aged from 23 days to 7 years; 50 per cent. were admitted to hospital more than one week after the onset. The age was not over 3 months in 17.6 per cent., and 67.6 per cent. were in the first year of life. The disease occurred almost invariably in districts in which crowding, poverty, and poor hygiene were prevalent. Maternal nursing did not tend to produce immunity, as of 22 infants not more than 3 months of age 18 had been nursed exclusively up to the onset of the disease, of 27 aged from 3 to 6 months 21 had been nursed exclusively, and of 28 aged from 6 to 9 months 15 were still being nursed by their mothers when the first symptoms were noted. Muscular rigidity, especially of the neck and with or without retraction of the head, was present in 84.5 per cent., Kernig's sign was found in 41 per cent., and Brudzinski's sign in 36 per cent. Unexplained irritability, which was one of the most

valuable signs, was present in 62.5 per cent.; a bulging fontanelle was found in 56.6 per cent.; convulsions occurred in 29.4 per cent., nearly always at the onset; 11 per cent. had a haemorrhagic eruption. Herpes occurred in only two patients, both over 1 year old. There was no characteristic temperature curve, and fever was frequently absent in the active stages of the disease. Vomiting occurred in 56.6 per cent. and diarrhoea in only 2 per cent.; tache cérébrale was noted in 20.5 per cent. Strabismus, present in 20.5 per cent., was the most frequent ocular manifestation of the disease.

## 546. Haemorrhagic Disease of the Newborn.

RUBY S. BEVERIDGE (*Arch. Dis. in Childhood*, February, 1928, p. 39) reports twenty-four cases of neonatal haemorrhagic disease treated in the Royal Hospital for Sick Children, Glasgow. She found that the sex incidence of the children affected was practically equal, and she remarks that it is in the first week of life, especially within the first four days, that bleeding is prone to occur. In only a small minority of cases was there any question of trauma at birth. She suggests that a determination of the coagulation and bleeding times would assist in the diagnosis between haemorrhage due to trauma and the true haemorrhagic disease. The most efficient and satisfactory treatment is said to be the injection of whole human blood, and transfusion is especially necessary where the constitutional symptoms are severe.

## 547. Pneumococcal Peritonitis in Children.

H. SALZER (*Deut. Zeit. f. Chir.*, February, 1928, p. 226) records his observations on 31 cases of pneumococcal peritonitis which have occurred at the Mauthner-Markhof Children's Hospital at Vienna in the last twenty years; twenty-eight were girls and only three were boys, the much greater frequency of the disease in the female being probably due to an ascending infection from the vagina. In twenty-one cases the correct diagnosis was made before operation. In the three boys the disease originated in pneumococcal appendicitis, but in none of the girls was a pneumococcal appendicitis present. One girl, however, showed a simple appendicitis due to *B. coli*, while a pure culture of pneumococci was obtained from the peritoneal pus. Salzer remarks that in the case of boys, therefore, it is not necessary to make a differential diagnosis between appendicitis and pneumococcal appendicitis, and an operation should be performed at once. In girls, however, an early operation should be avoided, as six out of eight girls so treated died, and a tonic treatment should be adopted. After the severe initial symptoms have subsided incision and drainage should be employed. By such treatment Salzer was able to save fifteen patients.

## Obstetrics and Gynaecology.

## 548. Menstrual Fistulae.

M. BALLIN (*Surg., Gynecol. and Obstet.*, April, 1928, p. 525), who records two personal cases with a review of the literature, applies this term to fistulae in laparotomy scars characterized by periodic discharge of blood, more or less coincident with normal menstruation. Although a few menstrual fistulae have been caused by a suppurating tubo or tubal pregnancy spontaneously rupturing through the abdominal wall, most are of post-operative origin, being caused either by direct communication with the uterine or tubal cavity, (1) following Caesarean section; (2) after operations for pelvic inflammatory diseases, salpingectomy, or partial hysterectomy; (3) after ventrofixation of the uterus, or by post-operative enclosure of endometrial tissue in the abdominal wall in the course of such operations as hysterectomy, ovariectomy, and ventrofixation. While there are on record at least 32 cases of menstrual fistulae following Caesarean section, examples of spontaneously formed fistulae from inflammatory conditions and tubal pregnancy are much rarer. Frequent complications with extensive intestinal adhesions and faecal fistulae occur; they render operation difficult and sometimes fatal, as in one of Ballin's cases.

## 549. Treatment of Amenorrhoea.

G. MAORTUA (*Arch. de med., cir. y esp.*, April 7th, 1928, p. 489) records three illustrative cases, in women aged 20, 22, and 40, suffering from amenorrhoea, who were treated by injection of the serum of a pregnant woman. The results were found to be far superior to those hitherto obtained by the usual method, including folliculin. Maortua is of opinion that the serum in pregnancy, in addition to an exogenous hormone, contains internal secretions, principally of the anterior lobe of the hypophysis, which explains the excellent results obtained. If the good results are confirmed by subsequent investigations he suggests that a serum might be prepared from pregnant animals which would be of value in practice.

## 550. Leucorrhoea.

F. IMPARATO (*La Gynéc.*, February, 1928, p. 65) does not agree with the five groups of vaginal organisms which Wegelius formulated. As a result of examining the vaginal flora in over 200 women the author finds that every case falls into one of three groups: (1) containing Gram-positive organisms with flat epithelial cells and scarcely any leucocytes; (2) containing coccobacilli, Gram-positive and Gram-negative staphylococci, and Gram-positive diplococci; and (3) large masses of cocci both Gram-positive and Gram-negative, together with flat epithelial cells. This last group never contains Döderlein's bacillus. Transition forms from one group to another were noted. Imparato remarks that the vaginal secretion is notably different in infancy, puberty, and old age. In the newborn there is a minimal secretion, which is acid and destitute of germs, but rich in glycogen, on which the acidity seems to depend. The glycogen diminishes slowly as the secretion becomes alkaline. At sexual maturity the secretion again becomes acid and contains numerous bacilli of Döderlein. The acidity is a natural protection against germs, and attains its maximum at the end of pregnancy. During the menopause the glands begin to atrophy and the reaction is feebly acid. Pathologically the vaginal secretion may increase and give place to an abundant leucorrhoea, milky, muco-purulent, or sero-sanguineous. As regards treatment, the outstanding cause must be treated, whether it be constipation, anaemia, lack of sexual hygiene, gout, or arthritis. The author enumerates the various kinds of local treatment which are in use, and for the typical leucorrhoea in which no appreciable cause is found he suggests douching with two small spoonfuls in a litre of water of a solution of zinc chloride 10 grams, distilled water 100 grams.

## 551. Pyotherapy in Puerperal Infection.

L. DEVRAGNE, SAUPHAR, and LAENNEC (*Rev. Méd. Française*, March, 1928, p. 195) remark that leucocytotherapy now occupies an important place in the treatment of certain infections, and many authorities, particularly Netter, are cited as having employed this procedure, the results obtained being due to the leucocyte diastases. There are two forms of this method of treatment: autoleucocytotherapy, in which a hyperleucocytosis is produced by excitation of the haematopoietic centres; and heteroleucocytotherapy, in which foreign leucocytes are introduced into the organism. The pus is obtained from an equine abscess of fixation caused by a turpentine injection. After repeated bacteriological controls and sterilizing in an oven a solution of uroformine (20 cg. per c.c.m.) in physiological saline is added to the pus to conserve its sterility when amputated. The authors report two series of cases of puerperal infection treated with excellent results by this method. In one series of fifteen cases the pus was given in curative, and in the other of five cases in prophylactic, doses. The dose employed by the authors was 4 c.c.m. daily, given subcutaneously in two injections, one into each thigh. In only one case, owing to the gravity of the patient's condition, was the intravenous route adopted. These doses were well tolerated and no ill after-effects were noted. The authors compare this treatment with that of abscess of fixation. Both are based on similar biological principles. In the one the introduction into the organism of irritant substances causes an abscess of fixation; the other involves the direct introduction of the pus. The advantages of pyotherapy are its easy administration, its harmlessness, and its being well tolerated.

## 552. Ectopic Decidual Tissue.

P. GEIPEL (*Arch. f. Gynäk.*, January 2nd, 1928, p. 650), who in 1921 described the finding of decidual tissue in the pelvic lymph glands during pregnancy, reports to the present date forty such findings in women dying during pregnancy and shortly after delivery; one case was that of a third gestation at the eighth week. About one-half the patients were primiparae; fourteen patients died from eclampsia and six from sepsis. Decidual deposit was not more common in young than in old subjects, and was found in about two of five necropsies on pregnant or lately pregnant persons. As a rule, one or two glands, usually on one side of the body only, were affected. The deposits were found in the reticular tissue of the follicles, in the capsule and trabeculae, and in the afferent lymph vessels outside the glands; true lymphatic tissue was destroyed indirectly by pressure, but endothelial tissue seemed insusceptible of decidual metaplasia or deposit. From the distribution of the decidual cells and for other reasons Geipel is inclined to believe that decidual transformation is due to the influence of a hormone diffusing from the peritoneal cavity; such an influence is comparable to that producing fat necroses in cases of pancreatic apoplexy. Decidual tissue was also found in the pouch of Douglas, in both omenta, or in the diaphragm (fourteen cases), and in one instance in the spleen.

## Pathology.

553. Cutaneous Spirochaetosis due to *Treponema cuniculi* in British Rabbits.

D. K. ADAMS, D. F. CAPPELL, and J. A. W. MCCLUSKIE (*Journ. Path. and Bact.*, April, 1928, p. 157) draw attention to a disease in rabbits which is liable to be confused with experimental syphilis. According to some observers as many as 20 to 40 per cent. of wild rabbits in this country are affected, though it would appear that in hutch rabbits the disease is much less common. The authors during the past four or five years have examined 228 rabbits, belonging to the laboratory stock; of these 14 were affected. The lesions consist of small scaly patches, often slightly eroded and covered with a brownish crust, situated on the genitals or in the perineal region. In males the peri-anal region was chiefly affected; in females the vagina and neighbouring skin. In two animals the nostrils were attacked; they showed deep erosions with raw, bleeding edges. In two others the disease attacked the eyelids, which were thickened and scaly. In all 14 cases spirochaetes were readily found, sometimes in enormous numbers. The organisms closely resembled *Treponema pallidum*, and, except for their being apparently rather longer, they were morphologically indistinguishable from it. Like *Tr. pallidum* the organism took on a rose-red colour with Glemsa's stain; in such preparations the two organisms were indistinguishable. Histologically the lesions were found to be superficial; no spirochaetes were demonstrated in the deeper tissues. The disease was readily transmitted from rabbit to rabbit by inoculation of an infective tissue suspension on to the scarified skin of the genital region. The incubation period varied from two to eight weeks. Once established infection persisted, often for months; in males spontaneous cure usually occurred, but in females, even though the large condylomatous lesions tended to heal, small scaly patches remained for a long time. Transmission by mating was effected, though not with constancy. The disease is readily cured by unguitum hydrargyri or by the intravenous injection of urosarso-nobillon.

## 554. The Pirquet Test—Puncture Method.

G. A. STEWART (*Amer. Journ. Dis. Child.*, March, 1928, p. 338) found, on applying the Pirquet test at the Lymanhurst school for tuberculous children, that the children preferred a single puncture through the skin to the usual scarification. A comparison of the efficacy of the two methods was therefore carried out on 281 children. The results agreed in all the cases, the same 223 children giving positive reactions both by the scarification and the puncture methods, while the remaining 58 were uniformly negative. The technique is simple: the forearm is cleansed with ether, a drop of tuberculin is placed on the skin and a single puncture made through the drop with an ordinary sewing needle. The tuberculin may be wiped off immediately after without appreciably altering the effectiveness of the test.

## 555. Sero-diagnostic Methods in Tuberculosis.

Y. E. BADOUX and Mlle M. NARBEL (*Rev. Méd. de la Suisse Romande*, January 25th, 1928, p. 21, and February 25th, 1928, p. 103) compare two methods and attempt to assess their value both from a diagnostic and a prognostic point of view. They describe in detail the method of Vernes in which 0.6 c.c.m. of clear serum is mixed with an equal amount of a 1.25 per cent. solution of pure resorcin. The optical density of this mixture is measured by means of a photometer. The authors have compared their results by this method with those obtained by Besredka's complement fixation test in conjunction with sputum and clinical examinations in a series of over 300 cases. They find that in 94 per cent. of cases the Vernes test is positive, as compared with 96 per cent. with the Besredka, and that therefore both methods are useful, although neither is infallible. They find that the Vernes test is of more value in prognosis than the other. It is also simpler, but the apparatus is expensive. In surgical cases its diagnostic value is 81 per cent. as compared with 61 per cent., and its accuracy in prognosis is said to be even more marked.

## 556. The Blood Groups of Children and Infants.

ELSIE CROWE (*Arch. Dis. in Childhood*, April, 1928, p. 114) records the investigation of the blood groups of 200 children. The first 100 were under the age of 12 and were normal boys and girls. The second 100 were infants under 1 year, many of whom were suffering from pneumonia, diarrhoea, and vomiting. The results show that infants as well as children have a definite blood group. In infants Group I contains a smaller and Group IV a larger proportion of cases than in children. This suggests that the blood groups may not be established during the early months of life. Sex and colouring have no apparent relation to the blood groups.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 557. Eczema caused by Quinine Suppositories.

K. HANSEN (*Tidsskrift f. d. Norske Lægeforening*, March 1st 1928, p. 215) recalls that, according to Moltzer's investigations, 0.12 per cent. of all human beings are liable to show some idiosyncrasy to quinine in the form of rashes and the like. This idiosyncrasy may appear not only when quinine is taken by the mouth, but also when it is used in hair lotions and suppositories. He records three cases of eczema provoked by quinine suppositories. The first patient was a woman, aged 23, suffering from an acute weeping eczema of the genitals and surrounding structures. She knew that she suffered from idiosyncrasy to quinine, which, when taken by the mouth, had several times provoked a rash, but she had not realized that the vaginal suppositories she had used contained quinine. The second patient was a man, aged 45, who had never had eczema previously, and who had suffered from acute eczema of the genitals, the inner side of the thighs, and the face. It transpired that his wife used vaginal suppositories containing quinine. Some time later, before the eczema had completely disappeared, the experiment was made of giving him 0.1 gram of quinine sulphate by the mouth. A few hours later an almost universal, violently itching erythema broke out, and the eczema in the inguinal regions flared up afresh. The third patient was a woman, aged 40, suffering from an acute weeping eczema of the genitals. She did not know that she was sensitive to quinine, but the eczema broke out after she had begun to use quinine suppositories. The author remarks that, considering how often quinine suppositories are used as contraceptives, and how common is an idiosyncrasy to quinine, it is strange that cases such as his have so seldom been recorded. He can, in fact, find only one such case, that of ZACHARIAS (*Méd. Klinik*, 1926). It is probable that the rarity of such records does not imply that this condition itself is rare; more probably it is fairly common, but often overlooked. It is characteristic of this condition that it begins on the genitals, that the husband or the wife suffers, but not both of them, that its severity depends on the degree of idiosyncrasy, that it extends to many other parts of the body if the use of the suppositories is continued, and that it is difficult to cure unless its cause is discovered.

### 558. Respiratory Hippus in Mediastinal Affections.

F. TONICETTI (*Il Policlinico*, Sez. Prat., March 5th, 1928, p. 307) reports three cases of alternate pupillary dilatation and contraction during inspiration and expiration. Koch, in 1903, reported a case of aneurysm of the arch of the aorta complicated with mediastinal, pleural, and pericardial adhesions in which this ocular phenomenon was continuous and bilateral, and gave it the name "respiratory hippus." Tonicetti remarks that the interpretation of the phenomenon is not quite clear. The first of his three patients had suffered for five months from difficulty of breathing, profuse sweating, violent cough, and scanty expectoration. He had a feeling of weight in the head with giddiness and persistent coryza. The neck then increased in volume, and his face and the upper part of the trunk were red and swollen. At night he often had severe attacks of dyspnoea. The jugular veins were markedly distended, and reticular veins were evident over the upper part of the thorax; the lymphatic glands of the neck were hard and fixed. The dyspnoea was intense, as was also the cough, owing to compression. The pupils were of normal size, symmetrical and of regular outline; their reactions to light and accommodation were singlish. Both pupils presented continuous and rhythmical oscillations in size synchronous with the respiratory act, dilating with inspiration and contracting during expiration. The phenomenon was not influenced by the size of the pupil in relation to light or accommodation; it occurred without jerks or interruptions. In Tonicetti's second case a hard indolent swelling appeared at the base of the neck in the region of the right carotid; and jugular distension followed with sensations of heaviness, heat, and giddiness in the head. An afternoon rise of temperature was followed by an evening fall accompanied by sweating. The pupillary movements were continuous and bilateral. Tonicetti's third patient had similar but less severe symptoms. The author considers that the last two patients had undoubtedly mediastinal lymphogranulomata with aneurysm of the aortic arch. In the first case, although he was sure of the presence of a mediastinal affection its exact nature was not quite clear. Tonicetti agrees

with Koch that the movements present no irregularity, and are not nervous affections. Kussmaul has reported a very slight dilatation of the pupil in normal man during the act of inspiration. The movements appear to be due to alterations in vascular pressure alone which affect the volume of the circulation in the iris.

### 559. Localized Asphyxia Due to Cold.

L. FERRANNINI (*Studium*, February 20th, 1928) reports an investigation into the etiology and pathology of a case in which local asphyxia was produced by cold. A woman, aged 30, with three healthy children, stated that when she was several months pregnant with her last child a fleeting cyanosis of the tip of the nose had been noticed. This coincided with a period of worry and anxiety. At the beginning of 1925, on a cold and windy day in the country, she had noticed a numbing of the exposed parts—hands, legs, face—which became first pale, then red, and finally blue. She was obliged to return to the house to restore warmth and feeling. This affection increased to the extent of preventing her carrying on her work as a domestic servant. At the end of 1927 she was admitted to hospital, and a blood examination revealed a diminution of red cells with a lymphocytosis; the Wassermann reaction was negative. When the patient's hands, which otherwise appeared normal, were submitted to cold air or cold water the skin became pale and the circulation ceased locally in a few minutes. When the cooling agent was removed the pallor remained for some minutes, after which blueness supervened. During the ischaemic stage the patient did not have any abnormal sensation, but there was diminution of tactile sensibility and difficulty in flexing the fingers was experienced. When warmth was applied the normal appearance was regained in gradual stages. The pulse and respiration rates diminished somewhat at the beginning of the local syncopal attack, but the amplitude and character of the pulse were not appreciably altered. The lower extremities, nose, and ears behaved similarly on exposure to cold. The question at issue was whether the condition was due to functional or organic alterations in the vessels. The capillariscopes did not reveal any marked changes from the normal, but investigation of the action of the vagus and of the sympathetic by means of injections of pilocarpine and atropine brought to light instability of the sympathetic. The possibility of endocrine disturbance was explored with Raynaud's "uterine cyanosis" in mind. Ferrannini concludes that this case represents a variety of Raynaud's syndrome, but adds that neither the etiology nor the pathogenesis of the condition is clear and no effective treatment has been found.

### 560. Iodine Deficiency in Water as an Index of Goitre.

D. F. SMILEY (*Amer. Journ. of Hygiene*, March, 1928, p. 297) has endeavoured to correlate the existence of slight degrees of goitre with iodine deficiency of the water supply. He examined two groups of students sitting for their entrance examination at Cornell University. One group showed enlargement of the thyroid gland; the other group did not. During the last seven years 967 male students in each group have been studied. It was found that of the first group 654, or 67.6 per cent., came from regions whose waters contain less than 23 parts of iodine per 100,000,000,000, whereas of the second group 555, or 57.3 per cent., came from such regions. This difference, in the author's opinion, is too small to be of significance. Since McClendon and Hathaway have shown that coarse cereals, green vegetables, and milk contain from 1 to 29 grams of iodine per ton of dehydrated food, even in regions where the waters are deficient in iodine, the author argues that iodine may frequently be ingested in sufficient quantity in foodstuffs to balance any effect of the iodine deficiency in the water. He therefore concludes that the iodine content of the water in a given region is not an accurate index of the frequency with which thyroid enlargement is to be expected in male students who come from that region.

### 561. Ocular Manifestations of Juvenile Tabes.

J. ROSNOBLET (*Journ. de Méd. de Lyon*, March 20th, 1928, p. 163) states that one of the principal features of juvenile tabes is the frequency of ocular manifestations such as changes in the pupils, oculomotor palsies, and especially optic atrophy. These ocular signs usually form the first evidence of the disease, juvenile tabes being first and foremost an amanrotic form, in which the cerebral symptoms predominate, whereas motor ataxia is ill marked or absent

and the general condition remains satisfactory. In 73 per cent. the pupils are unequal and often irregular in outline quite apart from the irregularity associated with the synchiae resulting from old iritis. In other cases the pupils are dilated and do not react to light or accommodation. The oculomotor palsies may be early or late. In the first group the levator palpebrae, rectus externus, rectus internus, and more rarely the rectus inferior and obliques are affected. The onset of these paralyses is rapid and recovery is quick and spontaneous, whereas the late paralyses, which are often bilateral and chiefly affect the third nerve, have a slow course and show no tendency to clear up. Optic atrophy has been noted in 53 per cent. of the published cases of juvenile tabes, and is thus twice as frequent as in the tabes of the adult. The atrophy, whether grey or white, primary or secondary to neuritis, invariably ends in complete blindness after an interval varying from a few months to a few years.

#### 562. Stammering Produced by Thyroid Medication.

M. B. GORDON (*Amer. Journ. Med. Sci.*, March, 1928, p. 360) asserts that tolerance to thyroid medication varies greatly, and depends on the autogenous thyroid content and susceptibility of the individual and not on his age or weight. The untoward symptoms produced by thyroid administration are essentially those of an acute thyroiditis, and are generally disturbances of the central nervous, gastro-intestinal, and cardio-vascular systems. Stammering may be produced by thyroid extract, and should be considered as a general nervous excitation following disturbance of the central nervous system. Five cases of infantile myxoedema and hypothyroidism are reported in which stammering occurred during the course of the thyroid treatment. The relationship between the stammering and the medication was emphasized by the subsidence and cessation of the affection following discontinuance of treatment. After a quiescent period of variable length, thyroid tolerance was later brought back by a gradual increase in the dosage. Gordon affirms that when stammering is noted during thyroid treatment, it should be treated as any other toxic symptom by immediately suspending the medication, which should not be resumed until some time has elapsed after the disappearance of the trouble and then only with small doses.

#### 563. Lymphatic Leukaemia.

D. L. FARLEY (*Medicine*, February, 1928, p. 65) reviews the classification of lymphatic leukaemias, their relations to other lymphatic diseases, and their treatment, especially by irradiation. In chronic lymphatic leukaemia the two characteristic features are the blood picture, with its increase of lymphocytes, and the histological structure of an excised lymph node, an unorganized hyperplasia of lymphatic cells of uniform size and appearance. In aleukaemic lymphoma or leukaemia, regarded by some observers as only a phase in either chronic or acute lymphatic leukaemia, the blood picture is lacking, while the lymph node presents the histological features described. In acute lymphatic leukaemia the lymph tissue may vary from normal to the chronic type, while the blood picture is marked. Most of these acute cases probably belong to the myeloid group. A true mixed leukaemia has never been definitely demonstrated in man. The author further draws a distinction between the lymphatic leukaemias and lymphosarcoma, leucosarcoma, mycosis fungoides, and Hodgkin's disease. Irradiation in leukaemia has been accomplished by the use of radium,  $\alpha$  rays, mesothorium, thorium-x, and various radium salts. The last three have been injected intravenously. The results obtained with radium in the past decade have been very promising. Bécère reported excellent results from using concentrated  $\alpha$  rays over the spleen in myelogenous leukaemia and over the lymphatic masses in the lymphatic type. Attempted irradiation of the bone marrow failed to produce any effects. X-rays or radium do not shorten the course of acute leukaemia of either type and may definitely accelerate the disease. Minot and Isaacs and Wood agree that chronic cases are benefited by irradiation; the improvement, though temporary, is often striking. The patient does not live longer, but he gains greater comfort and freedom from symptoms. Many other observers, however, consider that irradiation does prolong life in individual cases. A change to a different form of irradiation might be successful in resistant cases. Increase in the patient's sense of well-being and decrease in the size of the lymphoid masses or spleen appeared to be proportional. Generally, myelogenous cases reacted very much better to irradiation than lymphatic ones. The intravenous injection of mesothorium, thorium, or thorium-x is still in the experimental stage; control over this form of therapy is too indefinite. The technique employed in different clinics is described in an addendum to the review.

## Surgery.

#### 564. The Cerebro-spinal Fluid in Cranial Injuries without Fracture.

H. CLAUDE, A. LAMACHE, and G. DUBAR (*Paris Méd.*, March 24th, 1928, p. 271) review the facts known at the present time as to modifications in the physical and chemical state of the cerebro-spinal fluid induced by injuries to the skull insufficient to cause fracture, and record their own observations in twenty-two recent cases. The subjective symptoms most commonly noted by them in subjects of such injuries are, in order of frequency: headache, vertigo, asthenia, lusemia, tinnitus aurium, and visual fatigue. Chemical examination of the cerebro-spinal fluid included estimation of albumin, globulin, and sugar. Excess of albumin was found in nine cases and a fall in the albumin percentage was observed to take place gradually as the symptoms improved. Globulin was not detected in any case, and variations in the sugar content, always variable in normal subjects, did not yield any information of clinical value. Variation in tension was the most striking feature; in five cases only was the tension found to be normal; in the remainder tension was found either (1) raised (the greatest number), (2) lowered, or (3) unstable, varying considerably even in the course of a single observation; the authors note that such instability has been found by other observers previously in epileptics. Where hypotension is found lumbar puncture usually gives good results, though several punctures and the withdrawal of large quantities of fluid may be necessary. Where lumbar puncture is refused the ingestion of hypertonic saline and glucose solutions may be tried, though its efficacy is doubtful. In hypotension intravenous injection of distilled water has been tried, but the authors record one case of success following the apparently paradoxical withdrawal of fluid, possibly owing to stimulation of the mechanism of secretion. Treatment of instability of pressure has proved most difficult, but the trial of ergotamine tartrate is recommended. Variations in the cerebro-spinal tension are attributed to the liberation of toxins acting upon the secretory mechanism as the result of brain injury. Leakage of cerebro-spinal fluid into the surrounding tissues has been suggested as a possible cause of hypotension, but is not considered likely where no fracture can be demonstrated. It has been shown that the retinal pressure, as read by Baillart's ophthalmodynamometer, gives a close approximation to the cerebro-spinal tension, a useful alternative where lumbar puncture is refused.

#### 565. Reduction of Strangulated Hernia en masse.

J. CHAVANNAZ (*Rev. de Chir.*, No. 1, 1928, p. 33) records observations made in a series of cases of strangulated hernia reduced *en masse*. He concludes that reduction in this way is rare but not unknown, and that it occurs usually in adults and old people, men being affected more often than women. When reduction *en bloc* occurs it is nearly always the result of taxis by the patient himself or his doctor. It is most frequent in cases of inguinal hernia of long standing, particularly when on the right side and containing small intestine. The death of the patient is the usual result of a case which is neglected. Diagnosis is difficult, being often confused with intestinal obstruction. The chief characteristics on which it is made are the persistence of symptoms after reduction of the strangulated hernia *en masse* and the presence of a swelling in the region of the hernial orifice. Immediate operation is necessary, and the abdomen must be opened; in cases of gangrenous intestine there must be resection. Early operation is essential to success. In 1908 the death rate was 48 per cent. and is estimated now at 25 per cent., but it is probably lower since surgical intervention is more often undertaken.

#### 566. Primary Tumour of the Endocardium.

G. GULDBERG (*Norsk Mag. f. Lægevidensk.*, March, 1928, p. 272) records the case of a woman, aged 76, who had suffered for six months from symptoms resembling angina pectoris. At the necropsy a roundish tumour the size of a plum was found in the left auricle, as well as extensive arterio-sclerosis in the aorta and coronary arteries, fibrous myocarditis, and multiple pulmonary emboli. As neither the history nor the post-mortem findings gave any support to the view that the tumour could have been the cause of death its presence was regarded as a mere coincidence. It was situated on the lower margin of the closed foramen ovale, was brownish-red in colour, and of soft elastic consistence. On microscopical examination it was found to be a vascular fibroma interspersed with haemorrhages. There were no signs of any remains of thrombi in its formation, and Guldberg therefore had no doubt that it was a real tumour, confirming the view that the endocardium may be the seat of new growths.

## 567. Vasectomy in Prostatic Hypertrophy.

T. HÜHNE (*Zentralbl. f. Chir.*, March 17th, 1928, p. 642) remarks that the more serious sequelae of prostatic hypertrophy are residual urino, septic cystitis, and ascending secondary pyelo-nephritis. Renal back pressure may cause irreparable damage and ultimately uraemia. He considers that while prostatectomy is the preferable operation if the patient's condition permits, the post-operative mortality may be diminished further by more rigorous selection of cases. As a preliminary or alternative to the major operation he recommends ligation or resection of the vasa deferentia, which he has employed in thirty-six cases. As a preliminary operation vasectomy or ligation permits the use of a self-retaining catheter, before and after prostatectomy, without danger of secondary septic epididymitis or orchitis. The author found in his oldest patient, aged over 80, that the vas was patent. He recommends that one vas should be ligatured or resected, and then, after an interval, the other should be treated; this will lessen the danger of post-operative psychoses occurring. Hühne has performed vasectomy in fourteen patients aged between 66 and 85 without subsequent prostatectomy, which was contraindicated by renal insufficiency or advanced age. Six of these patients were treated subsequently by injection of the hypertrophied prostate with pepsin-novocain solution, as recommended by Payr. In four cases rapid improvement followed, and nine months later the patients were able to urinate normally. One patient had 20 c.cm. residual urine, the remaining patients had none. In the four patients the size of the gland was reduced from that of an egg or an apple to that of a chestnut. These results of the combination of vasectomy and pepsin treatment correspond with those of simple pepsin treatment. Two patients were not relieved by vasectomy and died from intercurrent diseases. Hühne concludes that vasectomy is a safe and simple operation which will prevent serious septic infection and may obviate the necessity for subsequent prostatectomy.

## 568. Treatment of Internal Haemorrhoids with Quinine and Urea.

W. A. ROLFE (*New England Journ. Med.*, March 15th, 1928, p. 187) describes the use of injections of quinine and urea hydrochloride in the treatment of internal haemorrhoids. As this method is painless and ambulatory it is well adapted to out-patient clinics, but care is needed in the selection of cases. Strangulated, sloughing, or external haemorrhoids should not be treated by this method, and spastic spasm, denoting infection in the ano-rectal region, is also a contraindication. Treatment should consist in six to eight injections at five or six days' interval, and the full course should be given even though bleeding is arrested by the first injection. Atrophy and ultimate disappearance of the pile follow successful treatment. There is no danger of complications, except that very rarely a patient may show symptoms of idiosyncrasy with vomiting and some collapse, but these quickly yield to suitable treatment. The injections should be given with the patient in the right or left Sims position; a Brinkerhof or Otis' rectal speculum is used to expose the haemorrhoid, which is swabbed with a 3 per cent. solution of mercurchrome, or, failing this, tincture of iodine. Some 5 per cent. solution of quinine and urea hydrochloride is drawn into a 5 c.cm. syringe, to which is attached a four-inch 25 gauge needle. Into the centre of each haemorrhoid 5 to 15 minims of the solution are slowly injected. Such injections should be made well above the recto-anal line, otherwise painful oedema may result. If rectal aching follows the operation it may be subsequently prevented by the addition of a drop of saturated sodium bicarbonate solution to the contents of the syringe. During the treatment constipation must be corrected by liquid paraffin.

## 569. Clinical Classification of Septicaemic States.

L. LANGERON (*Journ. de Méd. et de Chir. Prat.*, February 25th, 1928, p. 130) discusses the possibility of making a clinical diagnosis of the causal organism in septicaemia, of which he recognizes four main groups. His first group includes those cases in which the organisms give rise to the typhoid state; in his second group the septicaemia is the sequel of an obvious local sepsis such as puerperal fever. In his third type there is a dominant symptom, or group of symptoms, which would suggest a particular organism—as, for example, phlebitis causing a streptococcal septicaemia, or osteomyelitis a staphylococcal one. The fourth group comprises cases in which the septicaemia has no obvious or definite characteristic; in these the causal agent can frequently be suspected, though it may not be definitely established. In order to obtain an exact diagnosis the final appeal must rest with the pathologist, but the author remarks that it is always helpful for the clinician to be able to indicate in which direction the inquiry should proceed.

## Therapeutics.

## 570.

## Emetine in Amoebic Abscess.

THE value of emetine hydrochloride in amoebic hepatic or pulmonary abscess has not been generally recognized; although Leonard Rogers, more than ten years ago, advised aspiration of a "tropical" abscess and injection of the cavity through the cannula, with an aqueous solution of emetine hydrochloride (2 grains to the ounce). N. FLEISSINGER and R. CASTERAN (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, January 5th, 1928, p. 1746) record two cases of pulmonary abscess in which the symptoms disappeared rapidly after hypodermic administration of this drug. They comment on the great difficulty of diagnosing hepatic abscess when the pleuro-pulmonary syndrome simulates pulmonary congestion, pleural effusion, or empyema. Their first patient was an ex-soldier, aged 53, who was thought to have chronic diabetes with pleuro-pulmonary congestion at the right base. There was no albuminuria, but the sugar content was 33.3 grams per litre. The patient subsequently developed pyelonephritis, followed by violent pain in the much enlarged liver, and pyrexia. There was no history of dysentery, but he had served with dysentery-infected troops. Hypodermic injections of 0.08 gram of emetine hydrochloride were given daily for four days, and the dose was doubled on each of the four following days. The pain and fever ceased at once, and ten days later the polyuria and glycosuria had disappeared. He returned to work in three weeks, and four months later he had gained 11 lb. The liver was enlarged but not hard, the pulmonary signs had disappeared, and the urine was normal. The second patient, a man aged 33, was admitted with pleuro-pulmonary congestion at the left base. An amoebic abscess in the left lobe of the liver was mapped out by lipiodol; it contained 1.5 litres of pus and was cured by aspiration and emetine without incision. In two months the patient gained 22 lb. and resumed work. A. LEMIERRE and R. KOURILSKY (*ibid.*, January 26th, 1928, p. 37) report the case of a man, aged 46, who was admitted to hospital with slight fever and pain at the right base. At first he had no cough, but after a violent attack of coughing, with inodorous greenish sputum, excavation occurred, and the sputum became fetid and septic. Aspiration of the right lower lobe produced abundant greenish-yellow odourless pus. A daily hypodermic injection of emetine hydrochloride (0.08 gram) was given, and six days after the commencement of this treatment the patient's sallow, earthy colour disappeared. He gained weight rapidly and the temperature became normal. From the second day of treatment all fetor of the sputum disappeared.

## 571. Boric Glycerin Injections in Post-operative Anuria.

If urinary retention persists for about twelve hours after operation, E. FERNAUD (*Rev. Méd. de la Suisse Romande*, March 25th, 1928, p. 212) pursues the following treatment. A few drops of urine are withdrawn by catheterization, and then 10 c.cm. of a 20 per cent. solution of boric glycerin are injected into the bladder still full of urine; this dosage and concentration have been found to produce the best results. Twenty-eight cases are reported, in 24 of which the desired effect was produced in half an hour or less. In 15 cases only one injection was necessary, in 8 two, in 3 (in which spinal anaesthesia had been employed) three were given, and in only 2 cases were no results obtained and catheterization became necessary. Previously existing cystitis is said to be the only contraindication to this treatment, which is described as a simple, painless, and safe procedure, tolerated perfectly by patients. Fernaud insists that it is essential not to empty the bladder before making the injections, since injections into a void bladder are liable to cause haematuria or even nephritis.

## 572.

## Serum Therapy in Lobar Pneumonia.

R. L. GECIL (*Arch. Intern. Med.*, March 15th, 1928, p. 295), discussing the specific treatment of lobar pneumonia, submits evidence from his own work and that of others which clearly shows that antipneumococcal serum and its derivatives properly administered exert a definite influence on the course of pneumonia Types I and II. In pneumococcus infection in man the result depends upon whether the pneumococci or the leucocytes gain the supremacy, the infection remaining localized and recovery ensuing if the host produces sufficient immune bodies, whereas death from pneumonic sepsis results if the pneumococci produce sufficient soluble substance to overcome the immune bodies so that phagocytosis is inhibited, the infection spreads, and the pneumococci gain access to the blood stream. From a study of the Type I and II antipneumococcal serum of Cole, Hinton's antihody solution, and Felton's concentrated antipneumococcal serum it is concluded that the principle involved is the same in all. In a

series of 195 patients with Type I pneumonia. Colo found the mortality rate reduced two-thirds by treatment as compared with those untreated. Early and adequate treatment with large doses of serum is essential since the serum is bacteriostatic, producing an opsonization of the bacteria prior to their destruction by the leucocytes; thus by early and sufficiently continuous administration the soluble substance of the pneumococcus may become neutralized and a balance of immune bodies established with prevention of bacteraemia. The present difficulty in specific treatment is due to defects in the serum or its derivatives, so that purification and concentration are important factors in its practical application. Hinton's antibody solution, though free from horse protein, lacking sufficient concentration, while Folton's extract, though concentrated, is not entirely free from horse protein; both products may produce chills in large intravenous dosage. It is in Types I and II that the outlook for success with specific therapy is most promising. In Type III efforts to sterilize the blood by specific therapy have failed, the death rate being almost identical with that of untreated patients, and in Type IV specificity of the protective substance is impossible because a number of different types are concerned, so that a suitable serum cannot be made from a single strain of Type IV pneumococcus, though it might be possible to prepare a polyvalent Type IV serum by immunizing a horse against a number of strains.

#### 573. Artificial Light Baths in Tuberculosis of the Larynx.

A. FLUM (*Ugeskrift for Læger*, March 15th and 22nd, 1928, pp. 241 and 259) gives a statistical analysis of the results of the treatment of tuberculosis of the larynx with carbon arc light baths at the Elsen Institute in Copenhagen. His material consists of 163 patients whose treatment was started before January 1st, 1926, their records being completed up to January 1st, 1927. Practically all the patients had to be treated under ambulatory conditions, and many of them had to come to the institute from unhealthy homes, and had to make their way to the institute even though they were febrile and debilitated. The exposures lasted only fifteen minutes at first, being increased by fifteen minutes each time till the full exposure of two hours and a half was reached. As a rule, a light bath was given every other day, but women were often given daily light baths in order to make good the time lost during menstruation. For the most debilitated patients the initial exposure was only for ten minutes, and the increase of the exposures was comparatively slow. Among the 163 there were as many as 90, or 55 per cent., who were cured. In all other cases marked improvement, and in 20 cases some improvement, was effected. There remained 42 patients whose disease was unaffected or became worse. Relapses were infrequent, only eight relapses occurring among the 90 cases of recovery. The author points out, however, that the term "recovery" refers only to the disease of the larynx, and not to tuberculosis elsewhere, and in this connexion he admits that at least 14 of the 90 patients who recovered so far as their throats were concerned died subsequently of pulmonary tuberculosis. Also, among the 163 patients with tuberculosis of the larynx there were as many as 49 who died. A classification of the material according to sex showed that there were 99 men to 64 women. The recovery rate was considerably better for the latter, being 67.2 per cent., whereas in the case of the men it was only 47.5 per cent. The author suggests that this difference may depend chiefly on the fact that men come to treatment comparatively late because they are breadwinners with families to support, and because they often have to continue at work during treatment.

#### 574. Serum Treatment of Appendicitis.

WITH a view to establishing specific serum treatment M. WEINBERG, A. R. PRÉVOT, J. DAVESNE, and CLAUDE RENARD (*C. R. Soc. de Biologie*, March 16th, 1928, pp. 749 and 752) have made a study of the microbic flora in 150 cases of acute appendicitis, of which a great number were of the gangrenous type. The nitramicroscope showed that, in contrast with pulmonary gangrene, spirochaetes are rarely present in appendicitis; they were found in only three cases. Of the aerobic bacteria the frequency in the 150 cases was: *B. coli* 123, the enterococcus 41, *B. proteus* 14, staphylococcus 12, streptococcus 10; a few other species of organisms were found less frequently. Of the anaerobic bacteria the frequency was: *B. perfringens* 49, Gram-negative organisms 60, coccil and streptococci 40, *B. ramosus* 16, *B. fallax* 5, *B. bifidus* 2, *F. septique* 2, *B. histolyticus* 2, and other organisms in small numbers. The flora of the inflamed appendix is generally mixed, and consists of both aerobic and anaerobic organisms. The authors think that the flora varies in

ictant has been found very frequently, whereas in Franco it is uncommon. It appears that the two most important organisms are *B. coli*, which was present in 85 per cent., and *B. perfringens*, which was present in 30 per cent. of cases. As a result of this study the authors have replaced anti-oedematis serum by anti-coli serum, and they have prepared serums, for use in special cases, against *B. ramosus* and the enterococcus. The polyvalent serum is employed as a routine both for prophylactic purposes and to combat post-operative accidents. It is specially recommended for use in cases of acute appendicitis in order to lower the temperature and abate the symptoms, thus allowing the operation to be performed in a relatively quiescent stage.

## Anaesthetics.

575.

#### Sacral Block Anaesthesia.

J. S. LUNDY (*Amer. Journ. Surg.*, March, 1923, p. 262) finds that for many operations, such as those on the rectum, bladder, and perineum, sacral nerve-block anaesthesia is generally satisfactory. The patient during the injection is placed in the prone position, the hips being elevated. The skin over the sacrum is carefully prepared and a solution of procaine-adrenaline is used to produce the anaesthesia. A small skin-wheel is then made with a fine needle through which the caudal needle is to be thrust. This needle is then introduced through the sacro-coccygeal membrane into the caudal canal. The needle is advanced until it reaches the level of the second sacral foramen and as near the centre of the canal as possible. If spinal fluid appears the needle must be partly withdrawn till it lies below the dural sac. Twenty cubic centimetres of solution are injected into the canal, and while this is being done the respiration increases in depth. Anaesthesia occurs in thirty to forty-five minutes. If anaesthesia is incomplete it may be necessary to inject the first four sacral foramina posteriorly. In cases where the caudal canal cannot be located good anaesthesia can be produced by injecting twice the amount into the sacral foramina without a caudal injection.

576. S. A. WALLACE (*Canadian Med. Assoc. Journ.*, April, 1928, p. 406) compares sacral with spinal anaesthesia and surveys its anatomy, technique, and clinical application. Being a combination of caudal and trans-sacral block it affects the coccygeal and perineal regions, and the anus, rectum, urethra, and bladder. It is especially useful in cystoscopic work, litholapaxies, and stricture dilatation, as well as in rectal operations and prostatectomies. Though more difficult to perform it is said to be much safer than spinal anaesthesia; an accurate anatomical knowledge is essential. In caudal block 20 c.c. of a 2 per cent. novocain solution in normal saline with 10 minims of adrenaline per 100 c.c. is injected very slowly at body temperature through the sacral hiatus, and in trans-sacral block through the sacral foramina. Mild reactions are common, but severe ones can be avoided by slow injection, taking care that the needle is not in a vein or in the subarachnoid space. Wallace describes the technique for each procedure in detail, and points out that caudal block usually suffices for ordinary cystoscopic and urethral work, with the additional injection of the second and third sacral foramina in cases in which the bladder is inflamed and contracted. He adds that for haemorrhoidectomies and anal operations excellent anaesthesia results from caudal block with the additional injection of the lower foramina. For the more extensive operations of rectal resection and prostatectomies caudal block with injection of all the sacral foramina is required. In suprapubic prostatectomy an additional abdominal field block is necessary, and pre-operative narcosis by "twilight sleep" is indicated in apprehensive patients.

#### 577. Carbon Dioxide Administration during Ether Anaesthesia.

H. A. LAKIN (*Anaesthesia and Analgesia*, March-April, 1928, p. 85) relates his experience of using carbon dioxide in anaesthesia at over two thousand operations, and reviews the opinions of several other anaesthetists. For administering the anaesthetic Lakin employs a McKesson Model G apparatus, though he states that any other inhaler which has a rebreathing bag with stopcock attachment is suitable. The patient is first given pure oxygen or air, and the carbon dioxide is gradually added until it rises to 30 per cent. The ether administration is then commenced while the patient is getting this amount of carbon dioxide. Two methods have been tried with the same results: in the first, after the patient has taken eight to ten breaths of carbon dioxide, the ether indicator is turned

carbon dioxide is reached, the ether is turned on slowly to three-quarters or full, and the carbon dioxide flow is stopped. The respiration rate is an indication as to the sufficiency of the carbon dioxide given. Many advantages are claimed for this method. The induction to the ether anaesthesia is said to be smooth and pleasant, and the period is shortened, many patients being peacefully relaxed at the end of three minutes of ether inhalation. There is practically no struggling, excitement, choking, or breathlessness, and no cyanosis, patients always maintaining a good colour. Post-operative thirst is reduced, and nausea and vomiting have rarely been noted, even in gall-bladder operations. The depth of anaesthesia can be easily controlled, and de-etherization procedures can be used to hasten the return of consciousness and the elimination of ether.

#### 478. Ethylene Anaesthesia.

H. P. FAIRLIE (*Brit. Journ. Anaesth.*, April, 1928, p. 154) records his experience of ethylene anaesthesia in 200 cases. He considers that the danger of explosion when mixed with either oxygen or air is no greater than with certain similar mixtures of ether if the same precautions are taken; moistening the apparatus through which the mixture passes prevents such risk. The obnoxious smell, more obvious to those in attendance than to the patient, can be modified by the addition of eucalyptus oil or by securing greater purity of the gas. In administration a higher percentage (about 16 per cent.) of oxygen is required than with nitrous oxide, and McKesson's apparatus is preferred because it allows for rapidity of change in the proportion of the two gases and for the immediate delivery of pure oxygen if necessary. Fairlie regards ethylene as a safe anaesthetic provided there is not too strict a limitation of oxygen; he considers it superior to a mixture of nitrous oxide and oxygen, owing to the freedom from cyanosis and venous haemorrhage resulting from its higher oxygen content. Fewer patients require supplementary ether administration and a smaller amount is needed. It is an advantage to give a preliminary dose of morphine or of hyoscine-morphine. As to the depth of anaesthesia for producing satisfactory relaxation in abdominal operations, ethylene is said to be superior to nitrous oxide, and it has been frequently possible to anaesthetize with ethylene alone in cases where ether would have been necessary had nitrous oxide been the initial anaesthetic. The oldest patient was 82 and seven were infants a few weeks old; the series included 44 abdominal operations, 14 appendectomies, 7 gall-bladder operations, 5 gastrojejunostomies, and 4 hysterectomies.

## Obstetrics and Gynaecology.

#### 579. Placenta Accreta.

ACCORDING to M. RECH (*Gynéc. et Obstét.*, February, 1928, p. 81) the gravity of placenta accreta ("true adherence of the placenta") is intensified by the fact that this condition cannot be diagnosed until the moment of intervention, when an attempt is made to remove manually a retained afterbirth. Its occurrence may perhaps be thought likely in the case of those who have had many children and have been subjected to repeated manual removals of the placenta or to repeated curettages (especially in the puerperium), in cases of myomatous or malformed uterus, and in those patients in whom pregnancy has supervened after a long period of amenorrhoea. At any rate the history of many cases has pointed to such etiological factors, which may be taken to indicate that ensuing pregnancies should be terminated in hospital. Of the 25 cases collected by Rech from the literature, in 6 only did the patients survive the condition of placenta accreta and its consequences—haemorrhage, shock, and sepsis. Of the surviving patients two were treated by subtotal hysterectomy, rupture of the uterus having been diagnosed in one; one by hysterectomy after laparotomy for placenta praevia; one by tamponage after laparotomy for placenta praevia; and one by tamponage after curetting following a five months' abortion. The sixth case with survival is now described by Rech; delivery was by Caesarean section. The patient, a 2para aged 24, suffered from violent abdominal pain, vomiting, pyrexia, albuminuria, and slight vaginal bleeding fourteen days before term; the uterine was distended and firmly contracted, and the os admitted the tip of the finger only. The case being regarded as one of partial detachment of the normally situated placenta, laparotomy was performed. The acute symptoms were found to be due to left peritoneal salpingitis with localized peritonitis. After the Caesarean section it was found impossible to determine a plane of cleavage for detachment of the placenta, which tore and left many cotyledons intimately adherent to the myometrium.

Subtotal hysterectomy was performed and the patient recovered. Examination of the specimen showed that in some areas the placental attachment was practically normal; others showed varying degrees of accretion, and the myometrium was greatly thinned towards the fundus. Microscopically in the areas of adhesion the placental villi were inextricably tangled with the muscular bundles; the decidua spongiosa was completely absent, and the compacta was for the most part lacking. Inflammatory reaction in the decidua basalis was absent.

#### 580. Dystocia due to a Large Foetus.

P. BALARD (*Gaz. Hebdom. des Sci. Méd. de Bordeaux*, March 11th, 1928, p. 165) discusses dystocia due to disproportion of the foetus and pelvis. He concludes that dystocia may be said to begin with a foetal weight of 9 lb. 14 oz., though the head is not always proportionate to the weight. Dystocia depends less on the absolute volume of the head than on its degree of ossification, or its failure to reduce satisfactorily, but excessive size of the shoulders creates the chief obstacle in delivery. The diagnosis of dystocia can be made in the later months of pregnancy when the uterus is found to be bigger than the time of pregnancy would suggest, twins and hydramnios being excluded. As regards the etiology, dystocia seems to occur only in multiparae, and generally at the optimum age, but heredity plays some part, and the author quotes from his own records the cases of a mother and daughter, both of whom had disproportionately large children. The breadth of shoulder is said to be inherited from the father. Rest on the part of the expectant mother is likely to predispose to a large child; syphilis, diabetes, and endocrine deficiency have been suggested as causes. Labour in these cases is very prolonged and fraught with danger to mother and child. True dystocia of the shoulders does not appear until after the head is born. Traction must then be avoided, and an attempt should be made to substitute the cervico-acromial diameter for the bis-acromial one. The posterior arm should be brought down, the head rotated, and the same manoeuvre performed with the other arm, now posterior—all with great rapidity. A frequent complication is post-partum haemorrhage. The prognosis of an undiagnosed case is bad. When the diagnosis is made in the later months of pregnancy the choice of treatment lies between induction and Caesarean section.

#### 581. Traumatic Pelvic Haematoma.

S. DI FRANCESCO (*Ann. di Ostet. e Ginecol.*, February 29th, 1928, p. 183) believes that traumatic haematomas in the pelvis are more common during than apart from the puerperium, and are more often encountered below than above the musculo-fascial pelvic floor. The majority of haematomas unconnected with labour are of small size, and with conservative treatment are, as a rule, spontaneously absorbed. Large haematomas usually cause considerable difficulty in diagnosis; operative treatment is required because of their slow absorption and the considerable danger which exists of their becoming infected. The case is described of a single, poorly developed girl, aged 16, with rachitic stigmata, who while labouring in a factory sustained a blow on the right buttock; in spite of pain and faintness she continued to work for eight days. The pain was felt from time to time in the abdomen, back, right buttock, and right groin; walking became difficult, and rectal and vesical tenesmus were noted. During three weeks' rest in bed under medical supervision slight evening pyrexia was noted, but no gross pelvic lesion was suspected until the introduction of a syringe into the rectum was found to be difficult and painful. On admission to hospital three months after the accident a swelling was found extending upwards to three fingerbreadths below the navel and presenting below in the perineum, causing the posterior and right walls of the vagina to protrude. The hymen was intact; the uterus was displaced upwards and to the left. Puncture from below gave issue to blood clot, from which staphylococci and streptococci were cultivated. Six hundred c.c.m. of odorous contents were evacuated from the haematoma by a 2 c.m. incision in the right anterior vaginal wall. It is suggested that the bleeding came from a branch of the right gluteal artery.

#### 582. Ovarian Tumours in Old Age.

R. MÜLLERHEIM (*Zentralbl. f. Gynäk.*, March 17th, 1928, p. 689) records the case of a woman, aged 72, who complained of swelling and pain in both breasts, from which tumour formation was absent. Severe uterine bleeding was noted a few days later. The uterus, previously known to be atrophic, was found to be of double the normal size, but curettings showed only benign endometrial hypertrophy; a tumour the size of an apple was felt in the left ovary. Microscopically this was found to be a columnar-celled carcinoma, partially cystic. A second case is recorded in which a woman, aged 69, had bilateral mammary enlargement,

uterine bleeding, and a solid columnar-celled carcinoma of one ovary; she survived operation for eight years. Clinically these cases confirm the importance, in cases of post-menopausal bleeding, of paying attention to the ovaries as well as to the uterus; similar cases were reported by Monlougnot-Dolérin in 1924, but in his patients the tumours were mostly benign—solid or cystic and sometimes intraligamentary. Mammary hypertrophy, it is said, has not previously been described as an accompaniment of ovarian tumour causing metastasis in old women; it may be regarded as confirming the view that the renewed uterine activity is due to hormone ovarigenous influences. Myometrial and endometrial activity in aged subjects suffering from ovarian tumours has been held to be correlated with the fact that such tumours either contain primordial ova or are of granulosa-cell origin. The cases described in this paper do not conform to these characters.

## Pathology.

### 583. The Leukaemias and Lymphomas.

E. L. OPIE (*Medicine*, February, 1928, p. 31) surveys the literature on leukaemia and aleukaemic lymphoma in animals. Leukaemias conforming with the types found in man are found in many, if not in all, domestic animals, and in small animals available for experimental studies. Aleukaemic lymphocytosis apparently occurs much more frequently. Experimental study of leukaemias, resembling those of man has been as yet unfruitful. There has been almost unanimous agreement that none of these diseases can be conveyed from one species to another. Evidence is wanting that leukaemia in mammals can be transferred to other animals of the same species, and the same can perhaps be said of aleukaemic lymphoma. The "infectious lymphosarcoma of dogs" is readily transmitted by natural means, like a contagious disease, or artificially, with material preserved in glycerol. No micro-organism has been found in constant association with them. Resistance which appears in animals with the tumour has some resemblance to that caused by bacterial infection. The nature of the disease is as yet undetermined. Multiplication of blood cells and their precursors may be stimulated more readily in birds than in mammals. Diseases occur in fowls which closely resemble human leukaemias, but are easily transmitted to other fowls. Aleukaemic lymphomata are not uncommon with transitions to myelogenous leukaemia on the one hand, and to anaemia with hyperplasia of the precursors of erythrocytes on the other, though it is doubtful if lymphatic leukaemia occurs. These various changes are transmitted by a single virus, which is ultramicroscopic and filterable. In this respect these leukaemias differ from mammalian ones and resemble certain malignant tumours of fowls (sarcoma of Rous).

### 584. Bacteria in Spinal Fluids.

RUTH GILBERT and MARION B. COLEMAN (*Journ. Lab. and Clin. Med.*, March, 1928, p. 547) report the bacterial findings in the spinal fluids of 284 cases of meningitis, the examinations covering a period of over seven years. The number of tuberculous fluids was relatively high, being 167, due perhaps to the fact that 89 of the patients were under 10 years of age. In thirty-one instances ten strains proved to be of bovine and twenty-one of human origin. Meningococci were isolated in only eighteen cases, and these corresponded serologically with the various type organisms. In accordance with the findings of other workers it was noted that meningococci isolated from sporadic cases were less uniform serologically than those found in epidemics. Pfeiffer's bacillus was found in twenty-three instances, of which seventeen were children 2 years of age or under, and no history of previous respiratory disorders was given. This type of infection is said to be indicated by the presence of large numbers of polymorphonuclear leucocytes and very pleomorphic Gram-negative bacilli, and a tentative diagnosis may be made on these findings. The mortality from influenza meningitis is high, but experiments on monkeys appear to indicate that, with early diagnosis, vaccine or serum treatment may be of value. Pneumococci were found in thirty-three and streptococci in thirty-five cases. In only three of the former was a history of pneumonia given; and of streptococci, two were from head injuries, 3 followed mastoid abscess, and 10 of the variety producing methaemoglobin. *B. typhosus* was found in one case. *M. catarrhalis* in two, and *B. pyocyaneus* in one case following a skull fracture. In four instances unidentified organisms, due possibly to contamination, were found. The authors draw attention to the relatively low incidence of meningococci in this series.

### 585. The Chlorides of the Cerebro-spinal Fluid in Meningitis.

G. C. LINDER and E. A. CARMICHAEL (*Biochem. Journ.*, 1928, vol. xxii, No. 1, p. 46) have made an examination of the chloride content of the cerebro-spinal fluid in four cases of meningitis—two tuberculous, one meningococcal, and one streptococcal. In health the concentration of chloride in the serum is 0.58 per cent. and in the cerebro-spinal fluid 0.73 per cent., the ratio of the two being 0.79. The reason for this difference is not clear, and attempts to explain it on physical grounds have not been altogether convincing. The fall in the chlorides of the cerebro-spinal fluid in meningitis has been attributed to an increase in permeability of the choroid plexuses, thus allowing the chloride concentration to approach that in the serum. In favour of this explanation is the fact that in meningitis certain substances such as fibrinogen, bile pigments, and complement appear in the cerebro-spinal fluid. Against it, however, is the fact that the decrease in chlorides in tuberculous meningitis from 0.72 to 0.55 per cent., for example, is unassociated with a great increase in protein in the cerebro-spinal fluid. The authors bring evidence to show that the fall of chlorides is not due to increased permeability of the meninges. They find that the fall in chlorides occurs almost equally in the cerebro-spinal fluid and in the serum. In the four cases the chloride content of the serum varied from 0.56 to 0.45 per cent., of the cerebro-spinal fluid from 0.61 to 0.52 per cent. The ratio between the two was 0.85 to 0.90. (According to the table given this ratio is the same as in health; but in the text the normal ratio is given as 0.79.) The authors conclude, therefore, that the fall in the chloride content of the cerebro-spinal fluid is dependent on a similar fall in the chloride of the serum.

### 586. Cell Changes in the Skin in Measles.

B. LIPSCHÜTZ (*Wien. Klin. Woch.*, March 15th, 1928, p. 365) has found that the filterable virus of measles produces definite changes in the cells of the skin during the rash. It affects primarily the superficial capillaries of the subpapillary layer, leading to proliferation of the cells round the vessels. There is also an inflammatory reaction in the superficial parts of the corium, and the boundary between the corium and epidermis is obliterated at certain points. Swelling and occasional vacuolation of the epithelial cells and sometimes diapedesis of leucocytes occur. The changes in the epidermis depend largely on the stage the rash has reached and the severity of the case. The most important and constant changes Lipschütz found, however, to be intracellular and to affect the nucleus of the cells; one of these is said to be normally present in each cell and to be quite distinct from the nucleus. In a number of the skin cells in measles the two to four centrocytes which ordinarily constitute a nucleolus are increased in number, and after an staining reaction, showing an increased affinity for haematoxylin. Similar changes have been found in monkeys, in whom typical symptoms of measles occurred eight to fourteen days after an injection of measles virus. Lipschütz considers these intracellular changes of particular importance, since other workers have found other characteristic intracellular changes associated with such filterable viruses as variola and varicella. He suggests that they should be of value in identifying possible cultures, and in studying the nature and mode of action of those filtrates to which other methods are inapplicable.

### 587. The Blood in Scarlet Fever.

A. LEONI (*Sperimentale*, January 12th, 1928, p. 641), from a study of 90 cases of scarlet fever and 55 other diseases, including measles, diphtheria, typhoid fever, varicella, and serum sickness, comes to the following conclusions. (1) Döhle's inclusion bodies occur in all diseases in which there is a slight leucocytosis, whereas in typhoid fever, which is characterized by leucopenia, they are absent. According to Leoni these inclusion bodies indicate immaturity and perhaps also degeneration of the leucocytes. (2) Amato's bodies (round or oval bodies in the neutrophil leucocytes), on the other hand, are found exclusively in scarlet fever and in no other infections or diseases whatever; their presence is closely connected with the acute stage of the disease. They are of considerable diagnostic value owing to the readiness with which they can be found, and to the fact that they are present in scarlet fever and in no other disease. (3) Eosinophilia does not appear to occur in scarlet fever, in which in the great majority of cases the number of eosinophils is almost normal. They are, however, diminished in number or entirely absent in severe toxic attacks, especially those which end fatally. (4) The leucocyte picture in scarlet fever constantly shows a neutrophil polymorphocytosis (80 to 90 per cent.) with relative lymphopenia (1 to 10 per cent.). In severe attacks immature forms, such as myelocytes and metamyelocytes, may be found in large numbers.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 588. Acute Syphilitic Phlebitis.

H. MORROW and N. EPSTEIN (*Arch. Derm. and Syph.*, March, 1928, p. 309), who report an illustrative case, state that phlebitis is one of the rarer manifestations of syphilis, the veins, in striking contrast with the arteries, appearing to enjoy a comparative immunity. In addition to the first case reported by Gilwood in 1860, the authors have collected forty-five observations of various forms of syphilitic phlebitis, which they have classified in the following three groups: early superficial phlebitis; nodular thrombo-phlebitis; and late phlebitis. Early syphilitic phlebitis, to which they confine their attention, may appear as an inflammatory process of one or more segments of a vein. It has a tendency to be multiple, involving the veins of more than one limb, and frequently progressing from one vein to another. The lower limbs are more frequently affected, the internal saphenous usually being attacked. The phlebitis develops within a few months of the chancre, and may accompany or even precede the early secondary rash. The local and general symptoms are usually so slight that the condition is readily overlooked; they may, however, be severe, giving rise to nocturnal pains and constitutional disturbance. The skin over the affected vein is usually reddened, and occasionally there is slight oedema. The limb may be swollen, but does not pit on pressure. Early syphilitic phlebitis has a remarkable tendency to recur, either in the original vein affected or in another vein in the same or opposite limb. Under specific treatment complete involution occurs in two or three weeks. Complications are rare, and only one case of embolism has been recorded. Early syphilitic phlebitis is much commoner in males than in females. Of 31 cases in which the sex was stated 27 were in males and only 4 in females. Strain and alcoholism are contributory factors. The chief pathological change is a proliferation of connective tissue in the sub-endothelial layer which causes protrusion of the endothelium into the lumen. The *Spirochaeta pallida* has never been found in the lesions. Early syphilitic phlebitis is distinguished from the phlebitis due to other infective processes by the lack of constitutional and local symptoms, the multiplicity of the veins involved, the tendency to recurrence, the rarity of embolism, and the prompt response to specific therapy. The authors' case occurred in an alcoholic blacksmith, aged 30, who developed phlebitis in the left calf in the fourth month of infection, the right calf being subsequently involved. Much improvement took place under arsenamine, but the condition recurred when he resumed his work; a second though milder recurrence developed later, but complete recovery followed.

### 589. Epileptic Variants.

DURING the course of twenty years' practice S. A. KINNIER WILSON (*Journ. Neurol. and Psychopath.*, January, 1928, p. 223) has noted a large number of cases which present similarities to epilepsy, but which nevertheless do not seem superficially to resemble each other. Close study of these, which he terms epileptic variants, dispels the idea that epilepsy is a self-contained and sharply delimited clinical entity, and indicates that their clinical signs must be considered physiologically. Epileptic phenomena grade easily from the motor convulsive seizure to psychical, sensory, or visceral symptoms of a highly disparate nature, and Wilson classifies epileptic variants into the motor, sensory, psychical, and visceral, illustrating each group with clinical examples. The motor group includes myoclonic or regional epilepsy, epilepsy <sup>partialis</sup> <sub>partialis</sub>, and inhibitory or akinetic which is by far the commonest variant, consists in irregular twitches of a limb in multimuscular groups. Epilepsy partialis continua, somewhat rare, differs from the former type in that the twitching is limited to one, generally a peripheral, segment of the body; twittings continue between the fits, and are not so much movements as irregular individual muscular contractions. Tonic epilepsy is characterized by tonic contractions only, to the exclusion of the clonic element; in these cases it is advisable to suspect an organic and localizable basis for the affection. Co-ordinated epilepsy includes those cases where the movements are co-ordinated and seemingly purposive, exhibiting the features of voluntary movements. But they are aimlessly repeated and never attain an objective. In inhibitory or akinetic epilepsy immobility forms a prominent

feature of the fit; an illustrative case is reported in which there was a clear transition from convulsive to inhibitory epilepsy, the former being classifiable as epileptic and the latter as cataplectic. Sensory variants are grouped as reflex, sensory, and affective. In the reflex type the seizure develops after an extrinsic sensory excitation, and the sensory sensation may represent the whole of the disturbance. Affective epilepsy is characterized by its development following extrinsic or intrinsic affective stimuli, and differs from reflex epilepsy in the definitely affective element of the excitants. Discussing psychical variants Wilson states that much of an ordinary fit may consist of phenomena in consciousness, and refers to the occurrence of bad temper in epileptic families. Visceral variants are possibly the outcome of physiological disorder localized largely in sympathetic centres to the exclusion of sensori motor phenomena of somatic type. One variety, vaso-vagal attacks, can be clearly distinguished, and the symptoms are referable to transient functional disturbance in the organs supplied by the pneumogastric nerve, and probably develop from disorder of the dorsal vagal nucleus in the medulla and of the juxtaposed vasomotor centre. In other types of recurring seizure the symptoms may represent some disturbance of third ventricle visceral centres with spread to similar centres in the floor of the fourth ventricle.

### 590. Chronic Paratyphoid Septicaemia.

E. R. GRAWITZ (*Munch. med. Woch.*, March 30th, 1928, p. 560) reports the case of a woman, aged 53, who had had attacks of severe pain in the splenic region for a month, was diagnosed as suffering from primary tuberculosis of the spleen, and had the organ removed. After the splenectomy general septicæmia developed with metastatic abscesses in the pleura and subcutaneous tissue, but recovery ultimately followed intravenous injections of solganol, an organic gold preparation. Examination of the spleen showed two large abscesses from which a pure growth of paratyphoid bacilli was grown. The strain isolated was a transitional form between the so-called Breslan and the Schöttmüller types. The remarkable variability of all paratyphoid bacilli, which has been constantly emphasized by bacteriologists, is considered to explain the unusual clinical course in this case.

## Surgery.

### 591. Metatarsal Fracture.

S. E. GOLDMAN (*Journ. of Bone and Joint Surg.*, April, 1928, p. 228) remarks that fractures of the metatarsal bones, due in part to indirect violence, are not uncommon and are often overlooked. Lesions of this type are met with in strenuous athletic activities and where violent muscular effort involving the feet is required. As the initial trauma may be very slight, these fractures may pass unnoticed unless x-ray photographs are taken. "March foot," as it is called, is commonly met with in the army, where long forced marches with heavy kit are undertaken; hence it is well known to military surgeons. Its incidence in civilian practice appears to be uncommon. The condition is the result of over-fatigue in weak feet, resulting in spasm of the muscles, which causes blood and lymph stasis in the tissues. As a result of this there is swelling of the soft parts and brittleness of the bone tissue, leading eventually to fracture. It may be noted that "march foot" may occur without fracture of the metatarsals, which is usually a later development. Goldman records a case in a civilian where the x-ray examination showed fracture of the second metatarsal bone. The treatment should be rest and massage.

### 592. Primary Tuberculosis of the Bladder.

A. ROMANI (*Arch. Ital. di Urol.*, February, 1928, p. 201), who records a personal case, illustrates the rarity of the occurrence of primary tuberculosis of the bladder by the fact that Leguen in his textbook states that tuberculosis of the bladder is always secondary, almost always following renal tuberculosis and much more rarely tuberculosis of the genitals. Jungano in 1920 collected all the cases hitherto published—namely, five in number—but none of them could withstand criticism. Romani's case was that of a man, aged 38, who for the last six years had suffered from difficult micturition which had gradually been getting worse. Forty days before admission to hospital he had profuse hæmaturia. Nothing abnormal was found on examination of the lungs and genitals,

## Neurology and Psychology.

### 598. Chronic Systematized Deliriums.

R. BENON (*Rec. de Med.*, 1928, No. 1, p. 33) defines a delirium, which is sometimes difficult to distinguish clinically from mania and dementia, as a system of ideas, coherent or confused, single or multiple, founded on hallucinations, illusions, or numerous extravagant interpretations, and accompanied by varied emotional manifestations which involve the general belief or full conviction. Deliriums, though of extreme diversity, present four points in common: they are chronic psychoses, and almost invariably incurable; they are systematized, this being sometimes perfect, sometimes more or less obscure, sometimes more or less incoherent; they never terminate in dementia or loss of memory and ideas, and the delirious syndrome is often difficult to follow, though the intelligence may be enfeebled or diminished; and all appear to have an emotional or passionate origin, even when they follow acute or subacute, toxic, or infectious deliriums—that is, the troubles engendered by the emotions always precede the appearance of the insane ideas. In the great majority of these cases ideas of persecution are the essential theme, though these may be veiled by ideas, as, for example, of grandeur, or may even totally disappear; they are sometimes accompanied by melancholia. Benon places these deliriums in five groups. (1) Hallucinatory delirium, the commonest form and the true persecution delirium of Laségue. Its evolution is marked by three periods: a period of incubation or crystallization, one of hallucinations, and one of ideas of grandeur. (2) Delirium with psycho-motor hallucinations, a rare form, in which the patient only hears inner voices to which he submits and which direct his general activities, sometimes dangerously. (3) Paranoiac delirium, also rare, is based solely on false recognitions of persons, places, and sounds. This paranoiac is not an illusion; the objects that cause the sensations are not altered or illudged by the senses, the patient merely confusing them with others which he remembers. (4) Intro-projective delirium, which is constituted by delirious paroxysms based on anxiety. Hallucinations are always absent, and there are incessant repetitions of anxious manifestations. (5) A delirium, styled *revendicatif*, with paroxysms based on joy. As in the preceding form, emotional deviation plays an essential part in the absurd beliefs of the patients, and hallucinations are never present. Benon considers that chronic systematized deliriums are as varied as men themselves; that pure forms are rare; and that the greatest number are atypical, corresponding to the systematized deliriums of Magnan's degenerates, and are caused by individual degenerative elements which are at once of a sensorial, emotional, and dysthenic order. Such an atypical case is fully described.

### 599. Post-encephalitic Respiratory Disorders.

W. A. TURNER and M. CRITCHLEY (*Journ. Neurol. and Psychopath.*, January, 1928, p. 191) remark that, though the respiratory disorders associated with epidemic encephalitis have been frequently described, no effort has hitherto been made to trace their sequels. A short review is given of the literature relating to a few cases which have been followed up for some time, and the authors report the end-results in 29 cases, most of which were treated at the National Hospital. The disorders noted were tachypnoea (the commonest variety), breath-holding (the next in order of frequency), yawning, blowing and sniffing, coughing, and bradypnoea. In 20 of the cases an association of varying degrees of Parkinsonism was observed, but in only 8 were psychotic changes seen. Age seemed to be a factor, fifteen patients being in the second decade of life and only one in the sixth; while males outnumbered females in the proportion of 21 to 8. The 1924 epidemic appeared to be responsible for the majority (23) of the cases. Post-encephalitic respiratory disorders are usually paroxysmal; diurnal variability is the rule, and no precipitating cause can be traced. Emotional stress is perhaps the most potent aggravating factor; concentrated effort may cause a diminution in the paroxysms, and intercurrent illness or noxious stimuli may divert the disorders. The act of calling has exerted an unfavourable influence in a few cases; but severe physical exertion as a rule has little or no effect upon the appearance of the respiratory troubles, and the ability on the part of the patient himself to cut short an attack is rarely obvious. Numerous physical and psychological stimuli may temporarily influence the severity of the disorder, but recovery does not depend upon any particular treatment, and improvement, when it occurs, seems to be spontaneous. Of the 29 cases only 2 patients showed complete recovery, in 10 the respiratory disorder was cured, but other manifestations were worse or unchanged; in 2, while the respira-

tory disorder improved, other manifestations became worse or remained unchanged; in 13 the respiratory disorder remained unchanged; and death occurred in 2 cases. R. G. GORDON (*Ibid.*, April, 1928, p. 340) reports in some detail a case of post-encephalitic respiratory disorder in which there was an apparent complete recovery. A young woman who had been under observation for twenty-one months had a definite history of derangement of sleep and interference with co-ordination of eye muscles; this, with the subsequent sequels of respiratory (panting) and violent conduct disorders, left no doubt that there had been a mild attack of encephalitis lethargica. No treatment, excepting the mildest form of psychotherapy, was given, and recovery was almost spontaneous.

### 600. The Brain in General Paresis after Inoculation Malaria.

W. L. BRUETSCH and M. A. BARR (*Journ. Nerv. and Ment. Dis.*, March, 1928, p. 209) report a case of general paralysis in a man, aged 56, who died seven days after the intravenous injection of 1.5 c.cm. of malarial blood during a paroxysm. The authors' conclusions are as follows. (1) The treatment of general paresis with inoculation malaria produces during the paroxysm histopathological changes in the brain, consisting in proliferation of the capillary endothelium. (2) This reaction of the reticulo-endothelial system is as intense as in typhoid fever, which has often been followed by good remissions in general paralytics. (3) The absence of the perivascular infiltrations in the present case suggests the disappearance of the infiltrating cells during the acute malaria. (4) The perivascular infiltrations persisted in the temporal lobes and the corpus striatum. These findings accord with the observation of other authors on the modified distribution of the inflammatory phenomena following malaria. (5) During malaria, and particularly at the time of the febrile attacks, plasma cells probably immigrate into the brain vessels and take part in the phagocytosis of the liberated young plasmodia. (6) After retrogression of the perivascular infiltrations normal conditions are re-established in the perivascular lymph spaces, resulting in a partial recovery of the ectodermal tissue (ganglion and glia cells).

## Obstetrics and Gynaecology.

### 601. Necrobiosis of Uterine Fibroids.

ACCORDING to PATEL and DENIS (*Gynecol. et Obstet.*, March, 1928, p. 161), necrobiosis of a uterine fibroid occurs most commonly in women aged from 30 to 50, and is relatively frequent during pregnancy; the initial acute stage of the aseptic necrosis is known as red degeneration. Clinically there are two different symptomatic pictures, according as necrobiosis is slow or rapid, but intermediate cases are not rare. Slow necrobiosis is characterized by (1) an almost complete absence of local signs or symptoms and (2) vague general symptoms due to resorption of toxic material—malaise, digestive troubles, slight pyrexia (100.5°), and loss of weight. Rapid necrobiosis is associated with an acute pain in the lower abdomen which simulates torsion of an ovarian cyst, or an attack of pelvic peritonitis, and confines the patient to bed for a few days, thereafter gradually disappearing. There is also increase of volume of the fibroma, and alterations of the general condition are noticed, such as pyrexia, and thinning and yellowness of the face. The sequels of necrobiosis may be (1) calcification; (2) a continued condition of malaise and wasting which, if attention is not drawn to the pelvic organs, may be attributed to anaemia or tuberculosis; (3) an opening of the necrotic focus into the cavity uteri, with secondary infection and intermittent vaginal discharge—cancer of the body of the uterus may therefore be suspected; or (4) an infection by contiguity or the lymphatic route—the infected necrobiotic focus may secondarily open into the uterus or the peritoneal cavity. Necrobiosis of a uterine fibroid can be diagnosed with a considerable degree of certainty when a patient known to have a fibroid has abdominal pain accompanied by increased size and softening of the tumour, which becomes more tender. It may be suspected when a patient known to have a fibroid has slight pyrexia, wasting, and digestive disturbances, even in the absence of local signs. Gangrene or septic necrosis of a fibroid may be distinguished from necrobiosis in that the former is rarer, and occurs, as a rule, after a confinement or abortion or operation on the uterus; it is associated with high fever rigors, well-marked peritoneal reaction, and a fetid vaginal discharge. A single fibroid in a young woman may be removed by myomectomy, but, otherwise, hysterectomy is usually called for, and the prognosis is not worse than that of uncomplicated fibroids.

A subserous infected necrobiotic fibroid requires vaginal drainage after hysterectomy. When pregnancy is present with a necrobiotic fibroid expectant treatment will frequently enable the patient to go to term. When the symptoms do not abate it is necessary, according to the situation of the tumour and the duration of the gestation, to perform myomectomy, supravaginal hysterectomy, or Caesarean section followed by myomectomy or hysterectomy.

#### 602. Epithelioma following Subtotal Hysterectomy.

SIMONE LABORDE and ALICE ROQUES (*Bull. Soc. d'Obstét. et de Gynéc.*, February, 1928, p. 123) remark that the development of epithelioma in the cervix uteri following subtotal hysterectomy is generally considered to be somewhat exceptional. Nevertheless, among 379 uterine cancers they have met with this condition in 11 cases, the details of which are given. Taking as a basis the condition for which the subtotal hysterectomy was performed, they group these cases as follows. In the first class the cancer of the cervix developed after subtotal hysterectomy for an affection of the adnexa. In these cases the cancer was a Malpighian epithelioma, and developed at long intervals (from five to sixteen years) after the hysterectomy. In the second class the cancer developed after subtotal hysterectomy for fibromyoma of the uterus, and the neoplasms were again Malpighian epitheliomata. Here the interval between the hysterectomy and the development of the cervical cancer was much shorter, ranging from one month to three years. The third category comprised two cases of glandular epithelioma, one appearing a month after subtotal hysterectomy, performed on account of epithelioma of the body of the uterus, the other developing two years after subtotal hysterectomy for fibromyoma of the uterus. In this case the cancer may have been due to a malignant transformation in a tumour of the cervix already existing. The authors add that in general it may be said that the cancer in the cervix tends to show rapid development and an early spread to the vaginal walls. On account of their anatomical relations and the absence of the uterus, treatment by radium is said to be very effective. The occurrence of these cancers might be attributed to the fact that surgical intervention suppresses vascular and nervous, especially sympathetic, connexions and thus favours the development of cancer in an organ, the nutrition of which thereby becomes profoundly modified. The authors, however, consider its presence a pure coincidence in view of the frequency of cancer of the cervix, which should be taken into account in considering the relative advantages of total and subtotal hysterectomy.

#### 603. Diphtherial Endometritis.

L. LEFEVRE (*Journ. Amer. Med. Assoc.*, March 31st, 1928, p. 1015), who records an illustrative case, has collected three examples of diphtherial endometritis from the literature of the last twenty years. Two were reported by Lash and one by Beck. All presented great tenderness in the lower part of the abdomen, cramps or other abdominal pain, and in one case haemorrhage—symptoms which are absent in diphtherial vaginitis. LeFevre's patient was an unmarried woman, aged 21, who, on the sixth day of recovery from an illegal abortion, had a discharge of about a pint of bright red blood from the vagina, followed by a second severe haemorrhage a few hours later, accompanied by severe abdominal pain and tenderness. The pulse and temperature were normal. A large piece of placenta was removed from the uterus, which was packed with iodoform gauze. The following day the temperature rose to 100° and the pulse to 120. During the next four weeks the uterus and vagina were packed repeatedly, haemorrhage occurring every time the packing was removed. Finally, after a very alarming haemorrhage, the uterus was removed under gas anaesthesia, and the specimen showed post-abortive infection and non-resolution of the decidua. A culture of the uterine cavity after the organ had been removed produced a luxuriant growth of diphtheria bacilli and streptococci; 20,000 units of antitoxin were given, and rapid recovery followed without any paralysis. LeFevre recommends that culture of the uterine cavity should be made in cases of puerperal infection showing low fever and a markedly disproportionate increase in the pulse rate.

#### 604. Extrauterine Pregnancy.

ACCORDING to E. HAEUSERMANN (*Zentralbl. f. Gynäk.*, March 31st, 1928, p. 822) a greatly increased post-war incidence of ectopic pregnancy has been reported from several German districts. At the Städtischen Frauenklinik at Dortmund the incidence rose from between 10 and 20 annually from 1911 to 1918 to between 40 and 55 annually from 1919 to 1926. The increase is ascribed to the greater frequency of inflammatory disease in the Fallopian tubes as a consequence of increased commonness of criminal and

other abortions. In almost every case in the author's clinic diagnostic puncture of the pouch of Douglas is performed; the aspiration of dark-coloured non-clotted blood is regarded as characteristic of ruptured or aborted ectopic pregnancy. The prognosis is largely dependent on the earliness with which the patients come to operation; since 1921 there have been 259 recent non-infected cases with a mortality of 0.7 per cent., and 24 into infected cases with a 25 per cent. mortality. In the latter group of cases it is recommended that whenever possible the abdomen should not be opened until the pyrexia has disappeared, draining through a colpotomy opening being performed in the meanwhile if necessary.

## Pathology.

#### 605. Anaerobic Bacteraemia.

L. BOEZ, A. KEHLSTADT, and J. SCHREIBER (*Ann. de Méd.*, April, 1928, p. 340) recall that, while *B. ramosus*, described by Veillon and Zuber, has often been noted in gangrenous pus, it has only been isolated from the blood by Gilbert and Lippmann. The present authors, however, in 1924 recorded a case of bacteraemia due to this micro-organism, and now report seven further cases of a similar infection. In all these instances *B. ramosus* was isolated from the blood; in four innumerable colonies appeared in the cultures, and in three only ten to twenty colonies per 10 c.c.m. of blood were found. This bacillus is very delicate, and requires the strictest anaerobic conditions for its growth. It is a small, non-motile, non-haemolytic, and Gram-positive bacillus, growing with difficulty on Veillon's agar, and more readily on his asetic agar, but not at all on gelatin. It does not coagulate milk, but it ferments glucose and lactose though not maltose or saccharose. A serum prepared from a rabbit agglutinated the seven strains isolated in a titre of 1 in 500. The colonies are very small, round, and often punctiform. Of the seven patients, two died. One of these suffered from tuberculous meningitis complicated by a maxillary sinusitis from which a streptococcus and a *Staphylococcus aureus* were isolated; the other from a mastoiditis with thrombophlebitis of the sinus due to infection with an anaerobic staphylococcus. The authors remark that the part played by *B. ramosus* is not great; that its presence in the circulation does not markedly modify the clinical evolution of the disease; and that the prognosis in bacteraemia due to this microbe, as also in the majority of anaerobic blood infections, is governed by the initial infectious focus and its metastases.

#### 606. The Blood Urea in Scarlet Fever and Tonsillitis.

F. WAHLIG (*Klin. Woch.*, March 18th, 1928, p. 542) used Ambard's bromine and caustic soda method of estimation of the blood urea in forty cases of scarlet fever and five of tonsillitis, the blood being taken when the patient was in the fasting condition. Most of the scarlet fever patients were children aged from 3 years and upwards, and the adults were in the second or third decennium. The examination was usually made on the first to fifth day of the rash. Most of the cases were mild and only a few severe. The average blood urea value was 30.7 mg. per cent. In only four cases were high values found—namely, 78 mg. and 119 mg. per cent. In two cases of nephritis and 95 mg. per cent. in two cases without any abnormal findings in the urine. In view, therefore, of the fact that the physiological average blood urea ranges from 15 to 40 mg. per cent., it is held to be obvious that scarlet fever as such does not tend to increase the blood urea in the majority of cases which are not severe. Most of the cases of tonsillitis occurred in adults in the second, third, or fourth decennium. Their average blood urea value was found to be 16.3 mg. per cent.—that is, the lowest of all acute infectious diseases.

#### 607. Sterility and Vitamin Deficiency.

U. SUZUKI, W. NAKAHARA, and N. HASHIMOTO (*Japan Med. World*, February 15th, 1928, p. 31) refer to previous work on the factors governing reproduction in animals, and describe a series of experiments on white rats in which the effect of diet on reproduction was studied. The animals were fed on a diet practically free from fat and lipid, but adequate for growth. Prolonged observations proved that no reproduction took place among the test rats, though their general nutrition was good. The sex glands of the males became markedly degenerated, and on microscopical examination no spermatozoa were found. Small amounts of cholesterol or of synthetic triolein and daily exposures to ultra-violet light did not affect these results, the rats remaining sterile. As these diets are not deficient in any other known factor than vitamin E, these workers attribute the reproductive failure to the absence of this vitamin.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 608. Cardiac Insufficiency in Pulmonary Tuberculosis.

R. GONEL (*Presse Méd.*, May 12th, 1928, p. 596) gives an account of the syndrome presented by cardiac insufficiency supervening in patients suffering from pulmonary tuberculosis. Dyspnoea is the principal symptom of such an event, and varies from a slight degree of breathlessness with exertion to grave paroxysmal attacks in which the patient awakes during the night in great respiratory distress and expectorates abundant blood-stained sputum. Tachycardia, hypotension, and increasing numbers of râles are usually observed in such attacks; oliguria, thimtus, and subjective visual phenomena may be experienced. The x-ray appearances of the heart are frequently obscured by abnormal lung shadows and by cardiac displacement, but a marked convexity of the left ventricular border is not uncommonly found. Despite the difficulty of making electro-cardiographic records during attacks of this nature, tracings have been obtained showing left ventricular extra-systoles, isolated or in groups. The extent of the pulmonary lesion bears no relation to the onset or grade of cardiac insufficiency, although dyspnoeic attacks may mark the incipient stage of the disease or accompany the lighting up of an old lesion. This syndrome may also precede or accompany haemoptysis. Pathological examination of the heart reveals the left ventricle as being globular in shape and relatively large from hypertrophy in the majority of cases; the lungs show oedema, congestion, and sometimes haemorrhage surrounding cascating areas. Even severe dyspnoeic attacks are amenable to immediate treatment; ouabain should be given intravenously in daily doses of 1/4 mg. for three or four days. In the less severe cases it is preferable to give ouabain by the mouth in doses of 40 minims of a 1 in 1,000 solution twice daily for five or six days; since the effect of the drug is transient, this treatment should be supplemented by digitals in moderate doses. Camphor is sometimes beneficial. With regard to the induction of artificial pneumothorax, all signs of cardiac insufficiency must disappear before this is contemplated, and a look-out should be kept for such signs after each refill.

### 609. Etiology of Angina Pectoris and Abdominalis.

D. DANIELOPOLU (*Zeit. f. Klin. Med.*, 1928, Band 107, Hefte 3 and 4, p. 397) considers that the term "angina pectoris" is still too indefinite, since many authors include incorrectly in this category cases of dyspnoea and acute pulmonary oedema. Daniélopou divides all cases of angina pectoris into the simple and the complicated, the former being subdivided into organic and non-organic types. He cannot accept either of the current theories of the etiology of this syndrome, which, in his opinion, is an indication of myocardial exhaustion due to intoxication rendering the sensory and motor elements unable to eliminate their waste products. This condition produces a transient myocardial circulatory failure, due to a series of reflexes which he terms "pressor reflexes." In this severe circulatory failure there are secondary factors: (1) coronary arterio-sclerosis; (2) coronary aphasia; (3) aortic dilatation or other deformities obstructing the coronary orifices and so diminishing the myocardial blood supply; (4) pathological changes in the cardiac plexus and aortic wall. Daniélopou has seen many cases presenting evidence of inflammatory aortic and coronary arterio-sclerotic degeneration, extensive peri- and intra-neuritic infiltration of the small scattered ganglia of the cardiac plexus, with changes in their nerve cells. A fifth predisposing factor is the generalized hyperexcitability of the vegetative nervous system and of the sensory visceral system, which prefigures the cardio-vascular reflexes to the production of anginal attacks. The determining factors are as follows. The anginal attack is the result of serious myocardial circulatory failure; the special predisposing factors are constant, while angina pectoris is paroxysmal. There must be a critical moment which determines the attack—in other words, the attack is due to direct myocardial circulatory failure, caused by some effort which imposes too great a strain upon the myocardial circulation. This condition may be induced by increased cardiac activity or diminished myocardial circulation, or by both. Effort is the usual cause of the former, especially when the patient has hypertension, which may evoke attacks when the patient is at rest. The increased cardiac activity may terminate in paroxysmal tachycardia. Some patients who have coronary arterio-sclerosis may have a typical anginal attack during an attack of paroxysmal tachycardia; this may

cease suddenly, while the tachycardia persists. Emotion or heated argument may determine an attack through simultaneous spasm of the coronary arteries and increase of the cardiac action. The author believes that there is a "fatigue phenomenon" in these cases analogous to that of the voluntary muscles. The myocardium is thought to be the site of the anginal attack, where the accumulated toxic substances irritate the sensory nerve-endings and the motor elements of the myocardium. This stimulates the heart to further effort and a "vicious circle" supervenes. Daniélopou suggests a similar etiology for abdominal angina; the circulatory balance is disturbed and severe abdominal pain follows. The pain is usually situated in the epigastrium, and radiates to the spine or the right hypochondrium; it is caused by increased peristalsis and tympanites. Attacks are frequent after meals and after strenuous exertion; they are occasionally complicated by melæna. In many cases the abdominal arterioles have undergone degenerative changes similar to those of coronary arterio-sclerosis. This hypothesis is supported by the fact that angina pectoris and angina abdominalis may occur in the same patient; occasionally the two syndromes occur alternately.

### 610. Subacute Infective Endocarditis in Children.

B. SCHLESINGER (*Brit. Journ. Child. Dis.*, January-March, 1928, p. 33) illustrates the extreme rarity of subacute infective endocarditis in children by the following statistics. During the last sixty-five years at the Hospital for Sick Children, Great Ormond Street, only 10 examples were found after death as compared with 349 necropsies on undoubted cases of rheumatic carditis with endocarditis over the same period. At University College Hospital only 4 out of 60 cases of subacute infective endocarditis were in persons under the age of 15, the average age at death being 33. Horder, in a series of 26 cases with positive blood culture, had only 2 in children. Among Blumer's 317 cases there was only one under 10 years and 54 in the second decade. Subacute infective endocarditis and rheumatic endocarditis often show a close resemblance in their onset, while signs which are specially attributed to subacute infective endocarditis occasionally appear in certain rheumatic cases such as enlargement of the spleen, purpura, and clubbing of the fingers. The characteristic signs of subacute infective endocarditis in children are prolonged high irregular pyrexia and embolic manifestations, both of which are rare in rheumatism. The pathology of splenic enlargement differs in the two diseases. Enlargement in rheumatism is caused either by a severe primary infection or by secondary infection. Splenic infarction, although rare in rheumatism, is invariably present in subacute infective endocarditis. On the other hand, acute pericarditis, so common in rheumatism, is exceptional in subacute infective endocarditis, although signs of old pericardial inflammation are often present.

### 611. Inhibitory Epilepsy.

S. A. KINNIER WILSON (*Journ. Neurol. and Psychopath.*, April, 1928, p. 332) maintains that many epileptic phenomena are inhibitory and not excitomotor in character; he discusses a case in which the restraint or inhibition of motor centres by epileptic sensory discharges was shown, and refers to two analogous cases. In the first case the sensory aura followed the usual course of cortical excitation—namely, from the fingers up the arm to the shoulders and neck, thence down the trunk to the leg and toes, and at the same time to the tongue and face. Motor function varied during the seizure, the affected limbs being flaccid at the outset and passing through a period of relative rigidity to recovery. When the limbs were flaccid they were also powerless, and volitional innervation returned with the tone. In three fits it was noted that during recovery from the absolute flaccid akinesia the limbs for a time exhibited a striking defective inhibition of the antagonists. This disturbance of the normal interaction of synergists and antagonists supports the view that such interference with reciprocal innervation is commonly of cortical site, and is not observable, or only exceptionally so, at lower physiological levels. Actual loss or diminution of the deep reflexes was not noted during the attack. Their exaggeration, the presence of ankle clonus, and, on one occasion, of a probable extensor response, clearly point to intracortical release synchronous with cortical inhibition. The development of temporary motor paralysis without spasmodic discharge must be assigned to lower activity of the motor centres involved—that is, to their inhibition. The author remarks that the recent elaborate investigations of Pavlov have conclusively proved how readily inhibition

follows stimulation, and how, in respect of cortical function, the two processes are constantly and continuously interacting and superimposed the one on the other. Epilepsy cannot create physiological processes that do not exist; at the most it can only distort the processes of the individual concerned, and an epileptic development may be a sudden inhibition of the man's own movements. Wilson emphasizes the parallels and resemblances between inhibitory epilepsy and other clinical states in which akinesia is a prominent feature. In a recent paper on narcolepsy and cataplexy he stressed the fact that "sleep" is a misnomer, and that the clinical syndromes are constituted rather by a state of immobility without loss of consciousness, and are only allied to cataplexy on the one hand and to epilepsy on the other.

#### 612. Pathogenesis of Influenza.

P. BAIZE (*Gaz. des Hôp.*, March 24th, 1928, p. 421) discusses the views held on the pathogenesis of influenza before the discovery of Pfeiffer's virus. He points out that the pandemic of 1918-19, due possibly to influenza being due to a filterable virus, *Bact. pneumosintes*, and other organisms met with in the disease, such as varieties of streptococci, pneumococci, spirochaetes, and special diplococci. He distinguishes two varieties of influenza—namely, (1) true or essential influenza caused by a filterable virus, possibly *Bact. pneumosintes* of Oltzky and Gates, and representing an excessively contagious disease, occurring in pandemics at more or less distant intervals; bronchopulmonary complications are extremely frequent and severe, and convalescence is protracted; (2) various seasonal ill-determined affections, such as rhinopharyngitis, laryngotracheitis, ordinary colds and catarrhal sore throats, which are improperly called influenza, and should be more suitably denominated para-influenza states. This group differs from influenza in not having an epidemic character and being much less contagious. Complications are rare and recovery is usually rapid. These conditions are said to be due to non-specific organisms localized in the respiratory tract.

#### 613. Diagnosis of Chronic Myocarditis without Cardiac Failure.

T. S. HART (*Amer. Heart Journ.*, April, 1928, p. 430) defines the term "chronic myocarditis" as including degenerative and inflammatory processes which are due mainly to arterial changes and infectious and damage the heart muscle. The first manifestations of this disease are usually those suggesting cardiac insufficiency, but in a certain proportion of cases the diagnosis may be made in the complete absence of signs of failure. That such cases occur is clear from the frequent finding of small myocardial lesions at necropsy where no cardiac defect had been suspected in life; further, such lesions may produce extra-systoles, auricular fibrillation, or alternation of the pulse, or even abnormalities of the heart-beat, which can only be detected instrumentally. If cases belonging to this group are followed up the diagnosis is not uncommonly confirmed by the subsequent appearance of definite signs of failure and by post-mortem findings. Three cases are described as examples of this group. In two of them auricular fibrillation, and in the third right branch bundle block, were proved to be present without any evidence of cardiac insufficiency; in all three, however, such evidence ultimately appeared. Many patients give a history or present signs strengthening a diagnosis of chronic myocarditis; for example, some etiological factor may be discovered or there may be precordial pain, cardiac enlargement, a murmur, abnormal or very unstable heart rate, or alterations in the heart sounds such as reduplication or gallop rhythm. The author emphasizes the fact that these cases are not common, since cardiac insufficiency usually accompanies myocardial damage.

#### 614. Ulcero-necrotic Glossitis in Scarlet Fever.

L. BERGER (*Monatsschr. f. Kinderheilk.*, April, 1928, p. 289), who records an illustrative case, remarks that, in contrast with ulcero-necrotic angina, a similar involvement of the tongue and buccal mucosa is a very rare complication of scarlet fever, Heuoch and Hetzer being the only writers who mention ulcero-necrotic glossitis as a complication of this disease. Hetzer recorded four cases in which ulcero-necrotic angina in scarlet fever was associated with more or less extensive involvement of the tongue; all ended fatally. Berger's case was a girl, aged 11½, who in the course of a severe attack of scarlatina anginosa developed ulcers, first on the sides and then on the back of the tongue and both lips. No diphtheria bacilli were found, and no benefit was derived from the intramuscular injection of diphtheria antitoxin. Gradual improvement followed and finally complete recovery occurred.

## Surgery.

#### 615. Pre-cancerous Changes in the Rectum.

J. P. LOCKHART-MUMMERY and C. DUKES (*Surg., Gynecol. and Obstet.*, May, 1928, p. 591) record their observations upon the pre-cancerous changes in the rectum and colon, and show from pathological and clinical data that cancer of the rectum is frequently preceded by chronic hyperplastic epithelial proliferations similar to those described by Lenthal Cheate as preceding mammary cancer. Adenomata of the mucous membrane of the large intestine are known to be peculiarly liable to undergo malignant changes, and an irregularly distributed hyperplasia, often only microscopic, has been shown to represent the first stage of such tumour formation. The authors regard the sequence of events in the development of cancer in the majority of cases as being: (1) localized microscopical patches of hyperplasia affecting an extensive area of the bowel; (2) the appearance of sessile adenomata scattered over the same area; (3) cancer development either in one of such pre-existing adenomata or in the neighbouring epithelium; and (4) the progressive enlargement and dissemination of the malignant tumour accompanied by retrogression of the hyperplastic changes and benign tumours surrounding the malignant growth. In the rectum such a pre-cancerous condition is distinguished by irregular patches of hyperplasia of the mucous membrane and adenomatosis. Every such hyperplastic patch, however, does not necessarily develop into an adenoma, nor every adenoma into a cancer, since the former may disappear and the latter may become pedunculated and be shed; nevertheless, a patient in whom such a condition of multiple adenomata is found on sigmoidoscopic examination should be kept under strict observation. The authors state that this pre-cancerous stage may exist for many years or may abruptly assume the invasive properties of cancer; with the development of the malignant tumour the neighbouring epithelial proliferations and benign tumours tend to retrogress and disappear, so that they are less evident in association with large malignant ulcers.

#### 616. Prostatic Hypertrophy.

G. J. THOMAS and E. W. EXLEY (*Minnesota Med.*, May, 1928, p. 297) discuss the technique of pre-operative and post-operative treatment of non-malignant hypertrophy of the prostate. Their experience suggests that conditions contra-indicating operation or indicating a definite method of procedure may be discovered by a careful examination of the past history and physical condition of the patient, and they have been in the habit of co-operating with the other members of the hospital staff in an intensive study of every patient requiring prostatectomy. Not only should particular attention be paid to the heart and kidneys, but foci of infection should be searched for and renal function investigated, with complete blood, x-ray, and cystoscopic examinations. Gradual decompression of the bladder with an indwelling urethral catheter as a one-stage operation is performed, a suprapubic drain being only needed if decompression is not accomplished within a reasonable time, and double vasotomy under a local anesthetic is recommended as soon as decompression is completed. The importance of protecting the patient from chill during an operation, so that pneumonia may be prevented, is emphasized. For obviating post-operative haemorrhage the authors advocate infiltration of the prostate before enucleation with novocain, stitching the mucosa edge, tying all visible bleeding points, and using in addition the Filcher bag. Vasotomy and the control of infection with mercurochrome have in their series reduced the number of cases of post-operative epididymitis.

#### 617. Plastic Surgery for Hernia.

A. COMOLLI (*Arch. di Chir.*, April, 1928, p. 109) reports ten cases of relapsing hernia cured by transplantation of part of the sartorius muscle. The author has made a special anatomical study of the nerve and vascular supply of the sartorius, and gives a long detailed account of his researches. He then describes in detail ten cases of relapsing hernia where he used part of the sartorius muscle to fill the gap. In every case the result was completely satisfactory and has remained so for three and a half years. The position and shape of the sartorius muscle make it very suitable for plastic purposes in the lower abdomen, and the direction of its fibres and good blood and nerve supply render transplantation likely to be successful. The success of a graft depends largely on an accurate knowledge of the nerve supply, hence the author's careful description of this in the case of the particular muscle in question. He believes that some of the failures reported are due more to lack of knowledge in this respect than to sepsis. The paper is freely illustrated and a bibliography is appended.

# 618. Purpura Haemorrhagica following Fracture of Clavicle.

G. L. FRENCKELL and R. I. GAWRILOW (*Zentralbl. f. Chir.*, May 5th, 1928, p. 1037) describe the case of a man, aged 43, who sustained a comminuted fracture of the inner third of his left clavicle. Skiagrams showed that the bone was badly splintered; the mediastinal canal was opened and the diaphysis was impacted in the splintered epiphysis and also probably in the triangular cartilage of the sterno-clavicular joint. Four days after the accident the patient exhibited multiple subcutaneous haemorrhages over the left thigh and leg. On the next day petechiae appeared on various parts of the body, varying in size from that of a pea to areas 15 cm. in diameter. The petechiae began to fade in ten days and they had disappeared entirely in a month. The Wassermann reaction was negative. There were no symptoms nor history suggestive of haemophilia, purpura, or scurvy. The erythrocyte count and haemoglobin content were slightly below normal; on the first day there was leucopenia (3,600), monopenia, and slight eosinophilia. Subsequently the erythrocyte count became normal, the monopenia increased, and eosinophilia disappeared. Thrombocytes were very numerous (132,000) at first, but later they returned to normal. Many small nucleated erythrocytes (0.5 to 1 per cent.) were present; the coagulability was subnormal. The urine and faeces were free from blood. The authors refer to Verzar's recent discovery that extract of bone marrow has definitely haemolytic properties. They believe that when, in this case, the mediastinal canal of the clavicle was opened and the bone forcibly compressed some of the marrow was forced into the circulation and thus produced haemolytic phenomena.

# 619. Transplantation of Ureters for Congenital Incontinence.

G. A. MASON (*Arch. Dis. in Childhood*, April, 1928, p. 109) reports the case of a boy, aged 10, who suffered from incontinence of urine and complete epispadias. The ureters were transplanted into the sigmoid colon, one at a time. After each operation there was renal reaction and continence was established, the child passing his urine by the rectum four times daily. He seemed in perfect health. Three years later he developed obstruction from a band associated with tuberculous mesenteric glands, and died after the operation. At the necropsy the rectum showed a catarrhal inflammation of the mucous membrane below the entrance of the ureters. The right kidney was in a condition of advanced pyonephrosis, the left kidney was normal. Mason remarks that it is clear that after transplantation of the ureters a life may be lived which is to all intents and purposes normal. The rectum is able to tolerate the passing of urine, control is soon established, and voluntary evacuations are obtained at convenient intervals.

# 620. Tumours of the Renal Pelvis.

F. LEGUET (*Urol. and Cut. Rev.*, March, 1928, p. 140), who records four illustrative cases in patients aged 56, 64, 50, and 59, states that three varieties of tumour of the renal pelvis may be described—namely, non-papillomatous cancer, papillomatous epithelioma, and simple papilloma. Sessile non-papillomatous tumours are rare; simple papilloma is rarer in the renal pelvis than in the bladder, and degenerates rapidly into a malignant tumour. A characteristic feature of all tumours of the renal pelvis is their extension through a part or whole length of the ureter, so that they have often been revealed on cystoscopy by a tumour appearing in the bladder at the ureteral orifice. The predominant clinical feature of these tumours is haematuria, which, instead of being spontaneous as is usual with new growths, is often caused by examination and is usually accompanied by renal retention. Nephrectomy alone is not sufficient, but complete or partial excision of the ureter is also required to prevent recurrences, which take place in most of these tumours.

# 621. Intussusception in Children.

W. R. SHANNON (*Minnesota Med.*, April, 1928, p. 221) emphasizes the importance of early diagnosis. The cardinal points are: (1) pain, sudden and severe, first constant, later intermittent; (2) early nausea and vomiting (in 166 cases out of 170, according to Hess); (3) prostration, sudden and out of proportion to other symptoms; (4) tumour, the most important sign (Hess), present in over one-half the cases; (5) stools which contain blood in varying amounts after one or more normal evacuations; (6) temperature, which is typically not raised or subnormal in early stages. But any of these symptoms may be absent in a particular case. The author holds that blood in the stools is the most important individual sign, though many conditions other than intussusception give rise to it. The treatment is surgical, with the possible exception of an involvement frankly in the lower bowel, when x-ray studies could reliably indicate reduction.

# Therapeutics.

## 622. Treatment of Angina Pectoris by Alcohol Injections.

J. C. WHITE and P. D. WHITE (*Journ. Amer. Med. Assoc.*, April 7th, 1928, p. 1099) describe the use of paravertebral injections of alcohol in five cases of angina pectoris, the upper five left dorsal nerves being blocked; they have watched these cases for periods varying from four to thirteen months after the treatment. This is administered as follows. A 10 c.cm. syringe with thin sharp needles 8 to 10 cm. long is used, with a piece of rubber transfixed by it to indicate the depth to which it has been inserted, and the patient's position is as for lumbar puncture. Alcohol and iodine are used to disinfect the area, and a small cotton-wool pledget dipped in acriflavine is used to palpate and to mark the upper five dorsal vertebrae, acriflavine with iodine giving a black colour. A second series of marks is made 4 cm. to the left of the spinous processes, and a wheal is raised at each of these points by injecting 1 per cent. procaine. Through the wheal the needle is advanced perpendicularly to the plane at the back until, at 3 to 5 cm. depth, the underlying rib is felt; the needle is then shifted until its tip is felt to slip by the lower edge of the rib. It is then rotated so that it points caudally and medially 45 degrees, and it is then advanced forward a distance of exactly 2 cm. If one of the intercostal vessels is injured the needle must be withdrawn and reinserted. Five needles are thus put into position and aspirated to see if any blood or cerebro-spinal fluid is present. If the needle has penetrated the pleural cavity the patient will cough; a manometer can be used and the needle readjusted. An injection is now given of 5 c.cm. of 1 per cent. procaine; this should be followed by anaesthesia from the middle of the back to the sternum in front, and from the fifth intercostal space up to the region where the descending branches of the cervical plexus overlap the upper three ribs. If the first and second dorsal nerves have been properly blocked there should be good anaesthesia of the axilla extending a few centimetres down the arm, with Horner's syndrome—a contracted left pupil and narrowed palpebral fissure. When anaesthesia is complete 5 c.cm. of 85 per cent. alcohol is injected and the needles withdrawn. Four out of the authors' five patients were definitely benefited, but one in whom Horner's syndrome did not appear at the time of injection was unimproved.

## 623. Serum Treatment of Peritonitis.

J. KNOPP (*Zentralbl. f. Chir.*, April 14th, 1928, p. 923) has recently employed a *B. coli* serum in the post-operative treatment of ten cases of diffuse peritonitis and other kindred conditions. In two cases there were perforations of the gastro-intestinal canal, with severe diffuse *B. coli* peritonitis occurring twelve to fourteen hours after operation. Following the injection there was a rapid return of peristalsis with improvement in the general condition and the circulation. The serum was administered in four cases of diffuse peritonitis following appendicitis with perforation, with good results. In two of these cases the serum was given at a late period, after drainage had failed to arrest the progress of the peritonitis. In a subsequent case of *B. coli* peritonitis after appendicitis, the injection of serum produced severe anaphylactic shock; the treatment was not repeated, and the patient died next day. In the remaining three cases the administration of the serum failed. One patient had a *B. coli* metastatic pulmonary abscess, following perforated gastric ulcer, and another severe septic cholangitis. The third case was one of strangulated hernia, and the serum was given after operation. The infection had traversed the strangulated intestinal wall and possibly had caused slight peritonitis. The result of serum treatment was doubtful. Peristalsis was restored, but subsequently the patient developed severe hypostatic pneumonia. The author adds that the last three cases suggest that this treatment has limitations, although for diffuse *B. coli* peritonitis its employment seems to be clearly indicated.

## 624. Colloidal Bismuth in Syphilis.

L. DE KETSER (*Brussels-Medical*, May 6th, 1928, p. 886) reports the results of treating 66 cases of syphilis at various stages with colloidal bismuth. He places the cases in three categories for the purpose of comparing the effects of treatment. (1) In twenty-two patients who had not had any previous treatment the action of colloidal bismuth in primary and secondary syphilis was very slow and generally insufficient, but it was particularly efficacious in nerve lesions and especially in headache. Sixteen of this group of cases were tertiary, and in 4 of these the symptoms were ameliorated although the blood reaction remained unaffected. (2) Of 39 patients who had had previous treatment 8 had a negative Wassermann reaction, which remained negative even after

a course of bismuth. In 16 cases the previous treatment had not modified the blood reaction, and in 9 of these the bismuth did not appear to have any influence on the Wassermann reaction. In the others the results were good. (3) There were 4 cases of congenital syphilis, two of which had never been treated; in only one of these did the Wassermann reaction become negative. In another, although the reaction remained positive, a large ulceration of the leg cicatrized and albumin disappeared. The author concludes that there is no doubt that colloidal bismuth has a curative action on syphilis at all stages, but its action on recent primary or secondary lesions is generally slow. In two cases secondary lesions actually developed while the patient was under treatment. In the treatment of tertiary lesions ulcers and gummata are seen to disappear rapidly, and the action on the nervous manifestations at all stages is most marked, but especially in tabes. In two cases there was retrogression of optic neuritis after the second course of treatment. In about 50 per cent. of the cases a resistant positive Wassermann reaction was made negative. In certain cases in which this reaction had become negative under previous treatment it did not become positive during the cure with bismuth. The author comments on the freedom from danger in this treatment; only once was gingivitis observed after daily injections.

#### 625. Sodium Nitrite in Sea-sickness.

J. F. PEARCY and D. B. HAYDEN (*Journ. Amer. Med. Assoc.*, April 14th, 1928, p. 1193) report that during research on the labyrinthine function in relation to blood pressure it was found that by lowering the normal blood pressure to between 95 and 105 mm. of mercury the nystagmus after rotation was greatly diminished. Believing that sea-sickness is due mostly, if not entirely, to over-stimulation of the vestibulo, they concluded that the nitrites offered a direct line of attack on the morbid process in sea-sickness. Sixteen persons suffered from sea-sickness on a return trip across the Atlantic, and all had subcutaneous injections of adrenaline hydrochloride. For the test by sodium nitrite they were divided into two groups of eight. The controls were prostrated for the average two days, and there was not much variation from that period. The other group received 3 to 5 grains of sodium nitrite every two hours until relief. The average time before members of this second group were free from ocular nystagmus, vertigo, nausea, etc., and were comfortable on deck and could eat a meal, was four hours, and there was no recurrence. The authors agree that the series is a small one and think that there may be cases that cannot be dealt with successfully in this way.

## Radiology.

#### 626. Radiological Treatment of Uterine Fibromata and Hypertrophied Prostates.

H. B. PHILIPS (*Med. Journ. and Record*, March 7th, 1928, p. 238), discussing the x-ray and radium treatment of uterine fibroids and hypertrophied prostates, suggests that the similar histopathology of the two conditions affords a logical basis for expecting success from radiotherapy in both. In uterine fibroids his experience in two cases points to the fact that large size need not be considered a contraindication for treatment, since complete resolution without any disturbing symptoms resulted when the fibroids were larger than a six months and a full-term pregnancy respectively. X-ray treatment, in small doses of 20 or 30 minutes' duration on alternate days, is recommended until a suberythema dose is given on the anterior and posterior aspects; in very large tumours the sides are used for additional portals of entry in cross-firing. Persistent bleeding can be promptly controlled by supplementary radiation of the spleen and pituitary gland. An analysis of 65 cases shows that the earlier the treatment is commenced the quicker and more successful will be the cure, since failure is usually due to the superposition of such secondary changes as chronic cystitis and bladder atony. Large boggy prostates react favourably in all instances and are more easy to relieve than small hard fibrous ones; several prostates of the size of a small grapefruit have completely involuted to normal size. Philips concludes that radium or x-ray therapy is the treatment of choice, the former being used either exclusively or to supplement the latter; surgery should only be employed if these fail.

#### 627. Sodium Tetra-iodo-phenolphthalein in Radiology.

G. E. DYAS (*Brit. Journ. Radiol.*, March, 1928, p. 97) reports a death associated with the oral administration of this drug. A man, aged 52, previously diagnosed as suffering from gall-stone colic, was admitted into hospital in November, 1927. The liver was greatly enlarged and reached to the umbilicus; it was smooth and not tender, and the sclerotics were slightly

yellow. The only other abnormality was a high blood pressure (200/110). The patient had been a total abstainer for nearly the whole of his life. It was decided to have the gall-bladder x-rayed, and the patient was given sodium tetra-iodo-phenolphthalein by the mouth the night before; though apparently quite well a few minutes earlier, he suddenly collapsed and died after returning to the ward from the x-ray department. At the necropsy a linear tear about one inch in length was found at the most dependent part of the right lobe. Further examination showed evidence of advanced portal cirrhosis of both lobes, with, in addition, in the right lobe, acute degeneration of the hepatic coils and rupture of the walls of sinuses, as a result of the removal of the support normally afforded by these coils. The tear in the capsule presumably occurred as a result of the increased pressure within the liver brought about by the haemorrhage from the sinuses. The portal cirrhosis obviously played some part in the onset of the acute degeneration, but Dyas agrees that the relation of the tetra salt to the degeneration can only be conjectured.

#### 628. The Epilation and Erythema Dose of X Rays.

W. E. CHAMBERLAIN and R. R. NEWELL (*Radiology*, April, 1928, p. 280) have made a series of experiments on the relation between the hardness of x rays and their biological effect. Fricke and Petersen have shown that radiation  $\lambda = 0.75$  Angström has within 2 per cent. the same effect as radiation  $\lambda = 0.248$  Angström, but Glasser and Moyer found the erythema dose to be markedly dependent on the wavelength. In the present study epilation was chosen as being a precisely measurable effect, and erythema readings, largely a matter of personal judgement, were made for completeness. X rays of two qualities, filtered and unfiltered, were employed, and dosage was measured in the R units described by Bohannon. The experiments were performed on the anterior surfaces of the thighs of five young men, the left being treated with the unfiltered and the right with the filtered beam. The degree of both epilation and erythema was found to be practically the same for each kind of ray, and the dose delivered to a surface was augmented in every instance from the mass of material irradiated, or hard than for soft rays, and, while this becomes important when large masses are treated. The authors found that neither epilation nor skin erythema suffices to define x-ray dosage with satisfactory precision, and that the maximum safe dose is several times the minimum erythema dose.

#### 629. Radium Treatment of Cervical Cancer.

FOLLOWING a previous paper on the general technical principles underlying radium treatment of the carcinomatous uterine cervix, J. MUIR (*Med. Journ. and Record*, May 2nd, 1928, p. 472) now describes his own technique. He emphasizes that in this method precautions as to pre-operative preparation, rigid asepsis, and measures to avoid shock are as important as in surgical operations. Since this therapy is based on giving the highest possible dosage compatible with immunity of the surrounding unaffected tissues, proper applicators and suitable instruments for every step of the procedure are essential; protection for the rectum, bladder, and adjacent vaginal mucosa must be provided; and necrosis in the malignant tissue itself avoided. Pre-operative preparation includes the complete emptying of the bladder and rectum; just before the radium is applied the patient is given a thorough douching with normal saline or weak permanganate solution, and, if necessary, the anal is dilated. After the applicators have been placed in position the vagina is packed with gauze (on each side of the applicator) until the uterus and radium are well above and beyond the rectum and bladder. A catheter may be left in the bladder, or the urine drawn off every six hours. A firm T-bandage is applied and absolute rest is prescribed for forty-eight hours. At the end of the second day the applicators are withdrawn and sterilized, the vagina is douched, the rectum is emptied, and the applicators are re-introduced. This is repeated at the end of each forty-eight hours for six days and twenty hours—that is, for 164 hours in all—and thus is given a slow, intensive radiation so disseminated as to reach both the uterine periphery and the distal parts. Muir employs a much higher dosage, rendered possible by proper filtration, than is habitually used, the total irradiation being 7,900 millimicron hours, divided as follows: 2,200 millimicron hours from the intra-uterine tube, 3,800 from the pessary, and 1,900 from the cervical applicator. Muir maintains that the success attending this mode of treatment depends entirely upon the penetrating radiation made possible by the construction of the applicators, that the segregation of the hard gamma ray of the shortest wave length (the true therapeutic ray) is effected by the extraordinarily heavy filtration employed, and that slow intensive radiation gives the best results.

## Obstetrics and Gynaecology.

## 630. Heart Disorders in Pregnancy.

B. E. HAMILTON (*New England Journ. Med.*, March 29th, 1928, p. 292) reports that in the Obstetrical Clinic of the Boston Lying-in Hospital 7.5 per cent. of the patients are referred to the cardiac clinic for investigation. They are classified into three groups. The least important of these consists of patients complaining of breathlessness, palpitation, fainting, or heart pain. Nothing beyond tachycardia or extra-systoles is found on examination, and they are mostly cases of cardiac neurosis. The second class contains patients with possible or slight cardiac damage; rheumatic and slight congenital heart disease and mild infrequent paroxysmal tachycardias make up the majority of this group. Among 421 patients of this and the next class watched through pregnancy there was no occurrence of cardiac failure, and only two maternal deaths. The remaining class consists of patients showing such evidence of severe cardiac damage as gross cardiac enlargement, a diastolic murmur, significant disorder of the heart beat, and signs or history of congestive failure. Of 207 patients belonging to this group, there was a maternal mortality of 8.5 per cent. and an infant mortality of 22 per cent. The presence of any of the following complications is held to constitute an unsafe pregnancy risk: congestive failure past or present, recent or active rheumatic fever, active endocarditis, auricular fibrillation, uophris, and hypertension; under any of these circumstances the early interruption of pregnancy is advised. The avoidance of pregnancy, and sterilization if practicable, is suggested. As a result of improvement in the treatment of these patients the maternal and infantile death rates at the Boston Lying-in Hospital have been considerably reduced during the last four or five years. The following lines of treatment are recommended for patients in the last-mentioned class who are able to continue to term; during pregnancy ten hours in bed each night; much rest, particularly after meals; the avoidance of any but the lightest exertion, and if possible the prevention of any infection. Labour should be conducted in hospital, and if cardiac failure occurs the patient should remain in bed at least three weeks after all signs have disappeared.

## 631. Epidemic Encephalitis and Pregnancy.

F. ROQUES (*Journ. Obstet. and Gynecol. of the British Empire*, Spring, 1928, p. 1) discusses the reciprocal relations of epidemic encephalitis and pregnancy, using the notes of eighteen cases from the Sheffield epidemic (1920-24) and three London cases, as well as reviewing 200 cases collected from the literature of various Continental countries and America and from Scotland. In the largest series of cases the incidence among pregnant women did not exceed 2.7 per cent., and there is no evidence that pregnancy increases susceptibility. The mortality in Roques's English cases (18) was 5 per cent., but in larger series in France, Italy, and Great Britain it was from 44 to 60 per cent.; probably it is not as a rule greater on the average than that of all persons attacked under similar conditions of age, sex, time, and place. Primiparae are rather more commonly attacked than multiparae, probably because they are on the whole younger. In Roques's series all the infants were born healthy, and 85 per cent. survived the early months of infancy. Encephalitis in the newly born of mothers affected with the disease has been reported, but is very rare; transplacental transmission of the virus is proved by Marinisco's case, in which *post-mortem* examination showed signs of epidemic encephalitis in the brain of both mother and foetus (the mother was infected during the fifth month and died undelivered). To establish a diagnosis of epidemic encephalitis in the pregnant woman is easy, provided the signs are not too obscure and that an epidemic is known to be existent at the time. Mild cases, however, may be diagnosed as influenza, and the early stages may be confused with pregnancy toxæmia, eclampsia, or hyperemesis. Occasionally epidemic encephalitis mimics very closely the chorea of pregnancy, but in the latter condition the facial muscles hardly ever escape, and an onset later than the third or fourth month is rare. Artificial termination of pregnancy plays little part in the therapeutics of acute epidemic encephalitis, for miscarriage or labour rarely alters the course of the disease, and does not appreciably affect the mortality. Labour is sometimes found to occur with great rapidity and little pain; asphyxiation of a child born in hospital without the attendants' notice has been reported. The second stage should be completed quickly—by forceps if necessary—in order to avoid taxing too greatly the mother's strength; for the same reason suckling should be forbidden. There is considerable evidence that of women infected while pregnant a larger proportion become Parkinsonian than when the acute attack occurs without pregnancy. Whether this attack

occurs with or without pregnancy, Parkinsonism may make its first appearance during an ensuing pregnancy. Pregnancy in a Parkinsonian subject may be attended by an accentuation of the Parkinsonian symptoms. There is no evidence that Parkinsonism has an injurious effect on pregnancy, labour, or the puerperium, and little evidence that the child is morbidly affected. Regarding treatment of pregnancy in Parkinsonian subjects, Roques concludes that (1) prophylactically, those who have recovered from acute encephalitis should be advised not to become pregnant until four years have elapsed since recovery—the same advice applies to those first seen as Parkinsonians; (2) when Parkinsonian symptoms appear for the first time with pregnancy, induction of labour is justified and advisable; (3) in those who are Parkinsonian before conceiving, and in women who become pregnant after an acute attack but have not so far exhibited Parkinsonian manifestations, careful observation is called for, and deterioration or appearance of the signs of chronic encephalitis calls for termination of pregnancy.

## 632. Renal Function during Pregnancy.

ACCORDING TO G. DE CANDIA (*Ann. di Ostet. e Ginecol.*, March 31st, 1928, p. 293), it is wrong to reject the old concept of a "pregnancy kidney" with impaired function. Estimating the renal function by the phenolsulphonethylsulphate test and comparing the content in diastase of blood serum and urine, he finds that the variations shown by the two methods are without exception parallel. In normal pregnancy the renal sufficiency does not differ during the early months from that of non-gravid subjects. As pregnancy persists, however, both tests show a diminution of renal function, which is most marked at term and increases definitely during labour, returning to normal within the first days of the puerperium. Examination of renal function during pregnancy complicated by various maladies, including hyperemesis, tuberculousis, syphilis, nephritis, and renal calculus, showed in some cases an impairment which persisted after labour and was taken to point to permanent kidney damage.

## 633. Asphyxia Neonatorum.

M. HENKEL (*Zentralbl. f. Gynäk.*, March 24th, 1928, p. 730) protests against the application of forceps as routine treatment for asphyxia neonatorum. Since there are many causes of asphyxia, it is difficult to estimate its degree, and a hasty forceps delivery may mean unnecessary damage to the mother and injury or death to the child. Uterine contraction interferes with the supply of oxygen to the child; hence the acceleration of the heart, a process which is normal and shows the efficiency of the heart's response. Should the contractions become too strong or frequent asphyxia will supervene, and should be treated by lessening the uterine activity by morphine or chloroform. During expulsion the head may be unduly compressed and the brain injured, the cerebral centre may be upset either from lack of oxygen or irritation of the vagus, or from direct pressure. In any case the foetal heart is slowed, preventing the acceleration necessary to procure sufficient oxygen. Further, stimulation of the respiratory centre may lead to establishment of lung breathing, and, if the foetal circulation cannot be restored, the child dies. Henkel examines the foetal heart at frequent intervals and regards as danger signals slowing and irregularity in time and pace; to estimate the latter careful auscultation early in labour is necessary for comparative purposes. He adds that the appearance of meconium is of less significance than is usually supposed. Treatment consists of frequent observation of the foetal heart, administration of morphine or chloroform, or both, to control very strong contractions, and episiotomy of rigid perineum. In severe asphyxia no rule can be laid down; each case must be dealt with on its own merits, bearing in mind that the delivery of an asphyxiated child by high forceps defeats its own object and risks injury to the mother.

## 634. Rectal Gonorrhoea in Women.

L. SINGER (*Dermatol. Woch.*, April 14th, 1928, p. 506) comments on the divergence in the reported incidence of rectal gonorrhoea, and concludes that this condition is more common in women than is generally believed. It is often caused by urethral or vaginal discharge passing backwards towards the anus and, when established, seldom gives much discomfort. In recent infections there is pain and sometimes tenesmus during defaecation, anal pruritus, and the discharge of yellowish or occasionally of blood-stained mucus. In subacute or chronic cases pain is seldom present, and paraproctitic abscess is a rare complication. On account of the comparatively painless character of this condition its frequent occurrence has escaped recognition until recent years. Singer recommends that it should be treated by irrigation with silver salts in a viscid or gelatinous medium twice daily; 10 per cent. protargol suppositories are also said to be

very efficacious, usually curing the patient in two or three weeks, though, exceptionally, the treatment may have to be continued for six weeks. The author believes that in women the rectum is infected in approximately 38 per cent. of all cases of gonorrhoea. As a method of diagnosis and observation, irrigation is superior to swabbing, but the best results are obtained by alternating these procedures.

### 635. Induction of Labour by Pituitary Extract:

K. HATZKY (*Zentralbl. f. Gynäk.*, April 28th, 1928, p. 1055) reports seventeen selected cases in which he induced labour with pituitary extract. The patients were all at term with the membranes intact, and the pains had not begun. If primiparae were concerned the os was closed; if multiparae, it admitted one finger. The dose of the extract was 1 c.c.m. given in three stages at intervals of an hour—0.2 c.c.m. twice and 0.6 c.c.m. once. The results were: (1) Successful in 30 per cent., the patients being in labour within two hours of the last injection and the child having been born within twenty hours in the case of primiparae, and within twelve hours in the case of multiparae. (2) Doubtful in 11 per cent., labour having started but being prolonged. (3) Failure in 59 per cent., labour not having become established twenty-four hours after the last injection. The course of labour was not influenced by the injections, and serious complications were met with only among the failures. The puerperium was normal except for one case of mastitis and one of thrombosis of the pelvic veins. As regards the duration of labour, in the successful cases it was shortened to two-thirds of the normal; no further injections were given when labour had started, and this happened in some before the full dose had been given. The points in favour of the method are said to be its simplicity, the avoidance of risk of infection or complications, and the shortening of labour; the main disadvantage is its great unreliability. It is suited for patients who have reached full term, the child being fully developed, and there being no immediate hurry, so that in the event of failure there is time for other measures. It is of no value in the induction of premature labour or where time is important.

## Pathology.

### 636. The Pityrosporon of Malassez.

J. M. H. MACLEOD and G. B. DOWLING (*Brit. Journ. Dermatol. and Syph.*, April, 1928, p. 139), from an experimental study of the morphology, cultivation, and pathogenicity of the pityrosporon of Malassez, conclude that seborrhoeic dermatitis is a pure infection, and that, as is the case with other related fungi, the pityrosporon grows best in subjects with moist, greasy skins, and in such warm moist situations as the axillae, interdigital folds, scalp, and presternal and interscapular regions. Conditions of clothing or environment tending to provoke perspiration and sebaceous activity also favour its growth. It appears to be a frequent cause of anal pruritus and of serotol and inguino-crural dermatitis. Experimental inoculations varied in their effects upon the already existing disease, in some cases rapidly clearing up the lesions, in some causing fresh foci, while in others there was no response or reaction. The organism is pleomorphic, usually in the form of a gourd or flask with a large spherical portion surmounted by a small roundish process, or it may be hour-glass, ovoid, or sausage-shaped.

### 637. The H- and O- Forms of *B. typhosus*.

L. OLITZKI (*Zeit. f. Immunitäts.*, April 12th, 1928, p. 445) has studied the different antigens contained in the bacilli recovered from patients with typhoid fever and from convalescents. Of 23 strains of *B. typhosus* cultivated from the blood, 17 were of the H- or heat-labile form, and 6 of the O- or heat-stable form. Of 15 strains cultivated from the stools of patients, most of whom were in a late stage of the disease, only 3 were of the H- form, the remaining 12 being of the O- form. Likewise of 19 strains recovered from the stools of typhoid convalescents only 4 were of the H- form, the remaining 15 being of the O- form. Though no examination of the stools appears to have been made in the early stage of the disease, the author considers that during the stage of recovery from the disease there is a progressive change in the type of the infecting organism from the H- to the O- form. This would explain why in cultures taken from the blood in the early stages of the disease the predominating type is the H- form, whereas in stool cultures from convalescents the predominating type is the O- form. There is evidence that in certain chronic carriers the change in the organism may be even greater, and that some other antigen is elaborated, different both from the H- and the O- forms. In the actual

diagnosis of chronic carriers and of convalescents the author considers it advisable to put up suspicious organisms against both an H- and an O- agglutinating serum.

### 638. The Haemoclastic and Levulose Tests in Childhood.

MURIEL J. BROWN (*Arch. of Dis. in Childhood*, April, 1928, p. 81) reports the results of investigating the value of the haemoclastic crisis and the levulose tests in childhood. The first test depends on the physiological digestion leucocytosis. The author concludes that it gives most inconsistent results, both in normal and abnormal subjects. Regarding the levulose test, considerable variation was found in normal individuals, apart from the age of the child. It is considered that a rise of 30 per cent. in the blood sugar content after the administration of levulose should constitute evidence of hepatic disease. The purity of the levulose was of great importance. In most examples of definite hepatic disease the test was positive, but in ketosis and coeliac disease the liver appears to be normal, as indicated by the test. On the whole, where the clinical evidence left the diagnosis in doubt, the levulose test was of definite help.

### 639. The Reticulo-Endothelial System.

C. P. RHODES (*New England Journ. of Med.*, March 1st, 1928, p. 76) describes the reticulo-endothelial system as an organization of cells grouped together because of the common function of phagocytosis. It is made up of cells of somewhat similar morphology, and possibly of common origin; found in lymphoid tissue, spleen, liver, bone marrow, and connective tissue. The function of this cell group is very important for the following reasons. (1) It has to do with blood formation and destruction and with the formation of bile pigments. (2) It is active in combating infection, locally by phagocytosis and generally by the formation of antibodies. (3) It reacts specifically to certain infections, such as tuberculosis, leprosy, typhoid fever, typhus, rhonchatic fever, trench fever, and kala-azar, and takes part in processes of inflammation and repair. (4) It has an ill-defined relation to disordered lipid metabolism. (5) It probably forms a certain group of rare tumours variously termed reticulum cell sarcoma and endothelioma.

### 640. The Kahn Test in Primary Syphilis.

J. C. WILLETT and N. NAGLE (*Journ. Amer. Med. Assoc.*, April 14th, 1928, p. 1189) remark that only a small percentage of cases of syphilis show a positive Wassermann reaction during or before the second or third week following the appearance of the chancre. They claim for the Kahn test a marked increase in the positive reactions during the early primary stage, and they compare this test with the result of dark-ground examinations. In a series of 187 patients exhibiting venereal lesions, 105 were found by dark-ground and clinical examination to be cases of primary syphilis. Of these 105 cases, 84 gave a positive Kahn reaction, and in 64 the dark-ground was positive. In 39 cases the Kahn test was positive while the dark-ground was negative; the Kahn test was negative in 19 cases in which the dark-ground illumination test was positive. During the first week after the chancre appeared the dark-ground was most reliable, but in the second and subsequent weeks the Kahn test was the more reliable. The authors conclude that the Kahn test is a valuable diagnostic procedure in persons having a chance of less than one week's duration. It gave 80 per cent. positive as compared with 60 per cent. in the case of the dark-ground test. The primary lesions were of less than twenty-eight days' duration in all but four cases. The Kahn test failed in 20 per cent. of cases and dark-field examination failed in 39 per cent. of cases.

### 641. Passage of Arsenic and Bismuth into the Cerebro-spinal Fluid.

S. MUTERMILCH and Mlle E. SALAMON (*C. R. Soc. de Biologie*, April 27th, 1928, p. 1113), working with general paralytics, find that the injection by lumbar puncture of 1 to 2 c.c.m. of a sterile 10 per cent. emulsion of flour in saline gives rise to an aseptic meningitis, evidenced by a rise of temperature, headache, retraction of the neck, and Kernig's sign. When arsenic or bismuth compounds are injected intravenously into such patients the metals can be detected in the cerebro-spinal fluid an hour or two later; in patients without an aseptic meningitis this does not occur. In practice the flour emulsion was injected the previous day. The cerebro-spinal fluid withdrawn the following day was more or less turbid and contained a considerable number of polymorphonuclear cells. The quantity of metal that passed into the cerebro-spinal fluid was very small; two hours after injection it was never greater than 1 mg. per cubic centimetre of fluid, and generally very much less. The therapeutic results of this method of treatment are reserved for a further communication.

occurring in one out of 2,200 births. He considers the best time to operate, when the cleft of the palate is complete and involves the premaxilla and hard and soft palate, is between the first and third months. Repair of the soft palate should be undertaken between the ages of 18 and 24 months, before the child has learned to talk. Clefts of the lip should be dealt with between the ages of 3 weeks and 3 months. In premaxillary clefts a wire is passed through the maxilla above the alveolus and through the bone from the palatal side to the labial surface, the bones being moulded towards each other. The wire is removed in four to six weeks' time. The operation advised for clefts of the lip is a modification of that of Thompson, as described by Now of the Mayo clinics, and for closure of the soft tissue in palatal clefts a modification of the Langenbeck operation is said to give good results. Post-operative care is necessary to keep the child quiet, and compression sutures should be removed, beginning after the fourth day following the operation.

#### 648. Treatment of Fractured Ribs.

L. P. MARIANTSCHIK (*Zentralbl. f. Chir.*, May 12th, 1928, p. 1171) recommends for fractured ribs the application of a thin rubber bandage as being preferable to the ordinary method of fixing the chest wall by means of strips of plaster; he has employed this method in nine cases, one patient being a woman and the others males whose ages ranged from 40 to 75 years. In three cases the patients had fractured four to six ribs, in four cases two ribs were fractured, and in two cases only one rib was involved. In all cases the result was entirely satisfactory. The author's method is as follows. The patient's skin is disinfected and smeared with ointment or dusted with talc; he is then told to breathe out as completely as possible. A rubber bandage, three inches broad, is then applied spirally to the chest wall, commencing over the rib below the site of the fracture; each turn of the bandage is overlapped for half its breadth by the succeeding turn and the bandage is continued spirally to the level of the rib above the site of the fracture, when it is secured by covering it with a gauze bandage, the application being allowed to remain in position for a period of from two to four weeks. It is recommended that skiagrams should be taken after the application of the rubber bandage and before its removal, and that the chest wall should be subsequently massaged. A gauze bandage will give any support that may be required during convalescence.

#### 649. Late Treatment of Burns.

F. W. BANCROFT and C. S. ROGERS (*Arch. of Surg.*, May, 1928, p. 974) describe the successful treatment of severe burns by means of tannic acid. This treatment diminishes pain, prevents fluid depletion, decreases toxæmia, and, in first and second degree burns, permits epithelial growth while the membrane is in place. Among 114 patients treated with tannic acid the mortality from all causes was 20 per cent., while other methods showed a 40 per cent. or even 57 per cent. mortality. The treatment is as follows: morphine is given as soon as possible and combined with saline injections or transfusion. The skin is cleansed and that covering the blisters removed. After this, loose gauze dressings are applied which have been soaked in a 5-per cent. aqueous solution of tannic acid; they are kept in place for twenty-four hours, no bandages being used. When the burned area is tanned a mahogany brown the dressings are removed and a tent is erected, with electric lights to warm the air. Hyperbolic saline injections help to relieve toxæmia and prevent vomiting. Care must be taken to prevent infection under the tanned membrane, which after one or two weeks should curl at the edges and separate, leaving newly formed epithelium underneath. If, as is possible in a third degree type of burn, infection occurs, and the patient has an elevated temperature with gastro-intestinal disturbances, the membrane must be excised and hot boric acid dressings applied to the granulating area; this will become red and clean, after which epithelial growth should proceed rapidly. In deep burns skin grafts should be applied after the sloughs separate. For granulating areas which have been infected the scar tissue must be excised to the fascia beneath. Pinch grafts are usually successful if applied immediately.

#### 650. Diagnosis of Tuberculous Prostate.

H. BLANC (*Journ. de Méd. de Bordeaux*, March 25th, 1928, p. 226) thinks that the apparent rarity of this condition may be in part due to difficulties of diagnosis. He believes that it is often thought to be renal tuberculosis. It does not follow that tubercle bacilli in the urine are due to renal disease, and he quotes two cases of bacilluria in which the lesion was traced to the prostate by the use of appropriate methods. These methods are to wash out the bladder several times with a weak antiseptic, leaving it full. The patient then micturates, after which the prostate is vigorously massaged.

The patient then micturates again. The second sample alone will be found to contain tubercle bacilli. On cystoscopic examination in such cases there will be found a more or less normal bladder, with possibly an inflamed trigone. The prostate is not usually enlarged.

## Therapeutics.

#### 651. Promotion of Diuresis in Cardiac Conditions.

REGNIER, LEMORT, and MILLO J. VAN DEN EERHOUT (*Le Scalpel*, March 24th, 1928, p. 303) have tried mercuric acetate of salicylallylthiuril-O-acetate (salyrgan) in ten cases of heart disease, in view of the fact that many of these patients have anasarca and other signs of fluid retention which prove refractory to all treatment, whether cardiac or diuretic. Novasol yields satisfactory results in some cases, but its action is inconsistent, while several cases of nephritis following its use have been recorded. The authors state that salyrgan, which contains 35 per cent. of mercury, seemed to be a reliable and rapid diuretic. They administered it both intravenously and intramuscularly, either pure or diluted with physiological serum. The intravenous injections were usually well tolerated, but it was found that even a small quantity of salyrgan injected subcutaneously might produce scars, especially in old patients. No shock followed intravenous injections, but the vein might be obliterated. Intramuscular injections occasionally produced extensive aseptic infiltration, and, very rarely, large abscesses developed. Since unpleasant sequelæ occurred more frequently after intravenous injections, the authors have employed only the intramuscular route in their more recent cases. Diuresis lasted for twenty-four hours only when salyrgan was given intravenously, but for two days when injected intramuscularly. The quantity of urine is increased very rapidly—for example, from 40 c.cm. to 400 or 500 c.cm. every hour, in two or three hours after the injection; the average daily quantity was 3 to 4 litres, the maximum being 7.25 litres in twenty-four hours. One patient passed 700 c.cm. in an hour. The authors add that in a healthy man salyrgan does not produce diuresis. In all their cases the drug increased the flow of urine without provoking albuminuria or the passage of casts. If previously present, albumin and casts were not increased by salyrgan, even when twenty injections had been given on alternate days, but in all cases of nephritis in which this drug is used the urine should be examined daily for their presence. Cardiac oedema and ascites due to hepatic cirrhosis are both relieved by salyrgan. After a year's experience they regard this as the best diuretic in refractory cases of cardiac oedema, and they limit its use to these cases.

#### 652. Synthalin in Diabetes.

A. I. RINGER, S. BILSON, M. M. HARRIS, and A. LANDY (*Arch. Intern. Med.*, April, 1928, p. 453) discuss the use of synthalin in the treatment of diabetes; it is administered in doses of from 20 to 25 mg. twice on the first and third days, once on the second, and omitted entirely on the fourth day. An overdose causes anorexia, epigastric pressure sensations, nausea, vomiting, and diarrhoea. The authors treated four cases representing all stages of uncomplicated diabetes. They conclude that the drug has a decided advantage from the patient's point of view since it can be taken orally in tablet form, thus obviating the necessity for frequent hypodermic injections as required in the case of insulin; it is capable of clearing up glycosuria and ketonuria. Though insulin is considered ideal in clearing up hyperglycaemia, glycosuria, and ketonuria, in alleviating symptoms, and improving nutrition and well-being, it has the one disadvantage of possible hypoglycaemic reaction. Synthalin occasionally causes gastric distress, which Adler claims can be overcome by the administration of 0.5 gram of a sodium salt of dehydrocholic acid, which, acting as a bile stimulant, eliminates any unpleasant effects. It is unsuitable for emergencies since its action is slow, but it may be found useful in cases in which insulin is not desirable.

#### 653. Vaccine Treatment of Typhoid Fever.

H. SCHOTTER, S. BRODSKAJA, and G. SINAI (*Wien. Klin. Woch.*, March 1st, 1928, p. 297) state that, although more than thirty years have elapsed since Fraenkel, in 1893, introduced vaccine treatment in typhoid fever, the question of its efficacy is still unsettled. Stollkind, in 1916, collected only 3,416 cases that had been so treated up till then, and since that time comparatively few papers on the subject have been published, so that there is barely a total of 4,000 cases of typhoid fever in which vaccine therapy has been employed. During the period November, 1926, to July, 1927, the authors treated with vaccines 41 cases of enteric fever, of which 36 were typhoid and 5 paratyphoid, while 30 cases, of which 26 were

typhoid and 4 paratyphoid, were given symptomatic treatment only and served as controls. The results were as follows. (1) No encouraging results were obtained from the intramuscular administration of vaccine. (2) The intravenous injection of autovaccines caused only a slight general reaction and rendered relatively large doses possible, but owing to the time required for the preparation of these vaccines and the consequent delay in their application they were of little practical use. (3) The intravenous injection of a formalized vaccine composed of several strains was tried in 31 cases and produced a somewhat shorter duration of the disease than in 30 cases which had symptomatic treatment only. Systematic repetition of small doses did not cause any alarming symptoms, but it had no influence on the occurrence or character of complications, sequelae, or relapses. (4) The vaccine treatment of enteric fever is not to be condemned *a priori*, but needs further study.

## Disease in Childhood.

### 654. The Larynx in Whooping-cough.

F. HEINRICHBAUER (*Jahrb. f. Kinderheilk.*, November, 1927, p. 104) records his observations on the *post-mortem* appearances of the larynx in thirteen cases of whooping-cough in children aged from 8 weeks to 3 years. Four showed typical ulcers, which in three were on the vocal cord and in one in the interarytenoid space. In another three cases there was considerable inflammatory infiltration of the mucous membrane, which in the interarytenoid region had led to a perichondritis of the subjacent cartilage. In all the cases the capillaries were greatly dilated and the mucous membrane in the region of the sinns of Morgagni showed infiltrations which mostly consisted of round cells of the lymphocytic type. In several cases there were accumulations of lymphocytes, partly in a diffuse arrangement and partly in nodular form, often grouped around the openings of the ducts of the glands. Another change present in one case consisted in complete necrosis of the mucous membrane of considerable extent. In four cases the tissue of the vocal cord or its vicinity was loosened, and in another four cases round-cell infiltrations were found round the lobules of the glands. The origin of the ulcers which showed a typical localization in the vocal cord was undoubtedly due to mechanical factors, especially the knocking of the vocal cords against each other during the violent attacks of coughing. As the slightest irritation of the throat and larynx was sufficient to produce an attack of coughing, the author thinks that considerable importance must be attributed to the inflammatory lesions, especially the ulcerative changes. A vicious circle is thus formed by the attacks of coughing favouring the development of inflammatory changes in the vocal cords, and by the latter in turn provoking a paroxysm. He adds that the changes are not confined to whooping-cough, similar though isolated lesions being found in measles. The practical significance of the findings is that they furnish anatomical evidence of the duration and frequency of the individual paroxysms and of the duration of the disease as a whole.

### 655. Infantile Pyelocystitis.

G. VINCENT (*Arch. des Mal. des Reins et des Organes Genito-Urinaires*, February 1st, 1928, p. 239) describes two cases of pyelocystitis occurring in male infants aged 10 and 2 months respectively. The older child was admitted for a rhinopharyngeal infection complicated by intestinal disturbance. The urine contained albumin, and the mother stated that the child frequently cried when micturating. The temperature rose to 104° F.; there was cervical rigidity, Kernig's sign was positive, and the general condition suggested meningitis. The urine had a faecal odour, and contained numerous *B. coli*, polymorphonuclear cells, and granular casts. In spite of hypodermic injection of urotropine the temperature did not begin to fall for nine days, but four days later it was normal and the general condition had improved greatly. A week later the urine was apparently normal. In spite of repeated febrile attacks (apparently due to tonsillar or pharyngeal infection, relieved by ablation of tonsils and adenoids) there was no recurrence of pyelitis. The younger child, who was feverish and had persistent vomiting, had been sickled for fifteen days, and afterwards was fed on condensed milk. Three days before admission he vomited all food, was constipated, and the temperature rose to 102.6°. There was opisthotonos and diffuse cutaneous hyperaesthesia. Kernig's sign was present. The liver, spleen, and kidneys were palpable. The urine contained albumin, numerous polymorphonuclear leucocytes, granular casts, *B. coli*, and enterococci. The cerebro-spinal fluid escaped under pressure, but was sterile. Under autogenous vaccine treatment there

was temporary improvement, but the vomiting and diarrhoea returned and the child died from exhaustion at the end of four months' illness. The necropsy revealed no sign of tuberculous, but slight glomerulonephritis with pyelocystitis was present. The author remarks that in infancy boys and girls are equally susceptible to pyelocystitis, but in later childhood it is far more common among girls than among boys. Vincent adds that pyelocystitis results most frequently from acute gastro-intestinal infections, and to a less extent from acute or chronic bronchial and pulmonary infections. Other causes are nasopharyngeal infections, otitis media, and, occasionally, suppurative dermatitis.

656.

### Alimentary Pyrexia in Infants.

H. RIETSCHEL (*Med. Klin.*, December 9th, 1927, p. 1904) quotes experiments which show that deprivation of water in adults produces a rise of temperature during rest and an increased rise after physical exercise. Hyperthermia can also be produced in infants and others by the subcutaneous and oral administration of hypertonic saline solution. The following physico-dynamical explanation of the process is given. For every 10 grams of a 4 per cent. sodium chloride solution administered approximately 57 grams of water have to be withdrawn from the tissues in order to make the solution isotonic (0.6 per cent.) with the body fluids. By this "work" heat is generated, while the lack of water interferes with the loss of heat; the thirst produces restlessness and crying in the infant, thereby increasing the generation of heat, and pyrexia thus ensues. A similar result may be produced by insufficient water in young infants, and Rietschel thus accounts for the temporary pyrexia of breast-fed infants, frequently observed to reach its highest point about the second or third day after birth before the secretion of milk is fully established. This occurred in a larger proportion of one series in summer than in winter, and may be prevented by the administration of water. Loss of water is also probably an important factor in the production of pyrexia and the general toxic state associated with the more severe cases of infantile diarrhoea, which helps to account for the increased mortality from this condition during the warmer months. Rietschel also ascribes the fall in temperature which has been observed when bottle-fed babies with unexplained pyrexia are given breast milk partly to the lower salt content of the latter. The pyrexia of some infective conditions, especially in infants, is due to the cumulative effect of thirst and the infecting organism, and a rapid therapeutic effect is therefore often produced by the administration of water—as, for example, in pyelitis, influenza, and pyuria. Though water is very valuable in the treatment of pyrexia, especially in infants with poor appetites, the optimum amount must not be exceeded, as an excess of water also has deleterious effects and may produce digestive disturbances.

657.

### Sepsis in the Newborn.

R. VAGLIO (*La Pediatria*, January 1st, 1928, p. 1) deals with newborn infants who, after starting well, begin to lose weight, become pallid and bluish, are unwilling to feed, develop vomiting or diarrhoea, have a dry inelastic skin, sunken eyes, and occasional sudden rises of temperature, and often die suddenly. He believes that many of these cases are due to sepsis, and since greater care has been taken to avoid possible sources of it the results have been much better. He has abandoned the practice of early vaccination in these cases, as, he considers it to be a possible source of infection; the same applies to mouth cleansing. Any skin lesion, especially about the buttock, heels, and malleoli, should be carefully attended to. By careful prophylaxis on these lines the author obtained far better results than by measures directed to the cure of the sepsis itself, such as vaccine therapy.

## Obstetrics and Gynaecology.

658.

### Treatment of Vomiting of Pregnancy.

For the treatment of vomiting of early pregnancy and the prophylaxis of hyperemesis E. SPENDEL (*Amer. Journ. Obstet. and Gynecol.*, March, 1928, p. 411) recommends (1) prohibition of coitus, the patient occupying a separate room and resting during the morning; (2) a change of scene; (3) light meals of rusks, lemonade, feed tea, and sweetened fruit juice; and (4) intravenous injections of corpus luteum extract, exhibition of luminal sodium  $\frac{1}{2}$  grains three daily, tablespoon doses of milk of magnesia at bedtime, and in some cases (to combat hypochlorhydria) administration of ten drops of dilute hydrochloric acid in water before meals. An enema of a half gallon of warm water containing a tablespoonful of sodium bicarbonate will empty the colon and to some extent relieve the acidosis. If these simple measures are not successful

the condition takes the aspect of hyperemesis and demands energetic measures. The patient should be isolated from friends and relations, preferably in a hospital, and kept in a somnolent condition by rectal administration of 6 oz. of 10 per cent. glucose solution containing 60 grains of sodium bromide and 15 grains of chloral hydrate three times a day. To combat the dehydration one quart of decinormal saline solution should be injected daily under the breasts. Intravenous injections of glucose are most valuable: the solution must be prepared with pure glucose and freshly distilled water, and must be given warm. Half a litre daily in 10 per cent. solution is recommended; double the amount has been given to very dehydrated patients, but there is some danger of acute dilatation of the heart. Stronger solutions in smaller bulk have been advocated by Titus and others, but diuresis is to be avoided. A mixture with separately dissolved sodium bicarbonate solution (200 c.cm. of 3 per cent.) will help to diminish acidosis. In very severe cases a tube should be passed through the nose into the duodenum, where it can be left for several days, serving for the introduction of water, glucose solutions, liquid food, and laxatives. If intensive intravenous glucose treatment continued for four days is not successful duodenal treatment should be performed for a similar period. If at the end of that time decided improvement is not evident interruption of the pregnancy is justifiable.

#### 659. Glucose Treatment of Eclampsia.

P. TITUS, P. DODDS, and E. W. WILLETS (*Amer. Journ. Obstet. and Gynecol.*, March, 1928, p. 303) have found that whereas in normal pregnant women the blood sugar maintains a constant level for each person, an eclamptic patient shows repeated and rapid fluctuations. In the majority the blood sugar level is normal or reduced, except after the muscular exertion of a convulsion, and a convulsion is preceded by relative hypoglycaemia—that is, a rapid fall in blood sugar by from 15 to 80 mg. per 100 c.cm. within a few minutes. A causative connexion is traced between the onset of relative hypoglycaemia and of a convulsion; it is admitted, however, that an eclamptic convulsion may occur when the recently reduced blood sugar content is still at or even above the normal level, just as in certain circumstances diabetics may suffer from hypoglycaemic crises at average though recently and rapidly diminished blood sugar levels. According to the views of Titus and his co-workers, pregnancy is associated with diminution of hepatic glycogen by reason of foetal demands, hypertrophy of the uterus, and vomiting with insufficient diet during the early months of gestation. Pregnancy toxoses, such as hyperemesis and eclampsia, are attributable to disorganized carbohydrate metabolism; the associated nephropathy is incidental or contributory only, and the same may be said of the disturbances in nitrogen metabolism. Insulin treatment, which has recently been recommended for eclampsia—either alone or combined with injections of glucose—is contraindicated. Applying their conclusions to treatment, the authors recommend in pre-eclampsia restriction of salt and protein intake, but increased ingestion of carbohydrate, especially glucose with fruit juices. For eclampsia they advocate the injection of morphine hypodermically, magnesium sulphate hypodermically or intravenously, and chloral hydrate by the rectum. They also commend the intravenous administration of large single doses of hypertonic glucose solution—75 grams dissolved in 300 c.cm. of distilled water, the injection lasting from 60 to 75 minutes and being repeated at intervals of four to five hours during the attack and three or four times during the day following cessation of the convulsions. The immediate effects are diuresis, lowering of blood pressure, cessation of convulsions, and prompt regaining of consciousness.

#### 660. Fatal Staphylococcal Puerperal Infection.

LEMELEND and DARDANE (*Bull. Soc. d'Obstét. et de Gynéc.*, February, 1928, p. 132) record a case of labour at seven months, following a fall, in which a slightly macerated female foetus weighing 3½ lb. was spontaneously delivered. The same night the pulse and temperature rose, and all the signs and symptoms of acute puerperal infection were present. Fifty-eight hours after the delivery the abdomen was opened and total hysterectomy was performed. The reins in the utero-ovarian pedicles, being the seat of a thrombo-phlebitis, were ligatured. The patient's condition became worse, and she died on the twelfth day after delivery. On two occasions during the illness blood cultures revealed a pure culture of staphylococci. The authors sum up the points of interest in this case as follows: (1) the rapid onset of phlebitis; (2) the impossibility of performing a hysterectomy in acute puerperal infection; (3) the difficulty in fixing the diagnosis of a staphylococcal infection; (4) the lack of success of surgical intervention; (5) the unusual severity of a staphylococcal infection.

## Pathology.

#### 661. Chemical Changes concerned in Acidosis.

A. F. HARTMANN (*Amer. Journ. Dis. Child.*, April, 1928, p. 557) has studied the chemical changes in the blood of twenty-seven infants with mastoiditis who suffered from diarrhoea, vomiting, dehydration, and acidosis, presenting a clinical picture similar to that of alimentary intoxication. He found that the chemical changes were due to the chief symptoms of the infection—namely, vomiting, diarrhoea, dehydration, and oliguria. As a result of vomiting, hydrochloric acid and base chloride are lost from the body. Base bicarbonate is much reduced by loss in the intestinal secretion and diarrhoeal stool. Dehydration accounts for the occasional increase of lactic acid and protein, and oliguria for the increase of phosphoric acid and non-protein nitrogen in the blood. In a large number of the cases the blood was not examined chemically until after a considerable quantity of common salt, in the form of Ringier's solution, had been given intraperitoneally. In these cases the serum base bicarbonate and pH were much reduced, while the base chloride content was frequently greatly increased. Where the blood was examined before significant amounts of fluid were administered parenterally the base bicarbonate, although reduced, was not usually as low, while the base chloride was also reduced. The administration of large amounts of saline solution when diarrhoea and oliguria persist is therefore contraindicated, for it may produce extreme, persistent, and often fatal acidosis. Water in large quantity must be given orally as such, or intravenously as dextrose solution. Because of the frequent marked loss of base bicarbonate from the body intravenous administration of sodium bicarbonate is often indicated, and may at times be a life-saving measure.

#### 662. Temperature of the Cerebro-spinal Fluid.

P. SCHEFF (*Arch. de méd., cir. y esp.*, March 24th, 1928, p. 422) found that the average temperature of the cerebro-spinal fluid, as estimated by a thermo-electrical apparatus, was 37.68°C. in fifty patients with a normal rectal temperature. This result indicates that the temperature of the cerebro-spinal fluid is approximately half a degree higher than that of the rectum. The spinal temperature to a great extent appears to be independent of external agencies, such as analgesic or antithermic drugs or motor excitement. It does not appear to have a direct relation to the general temperature of the individual nor to the tension of the cerebro-spinal fluid. Ten patients showed an abnormally great difference, ranging from 0.9° to 1.5° C., between the temperature in the rectum and that in the spinal canal. Most of these patients were suffering from senile psychoses. The author thinks that it would be premature to draw any definite conclusions from these facts, as patients suffering from the same affections presented normal spinal temperatures. Eight patients who were suffering from an anxiety syndrome showed spinal temperatures which were the same as or lower than the rectal temperatures. These results were obtained under rigorously controlled conditions. The apparatus is delicate, costly, and takes up considerable space, and is not suitable for clinical use.

#### 663. The Brain in Encephalitis.

J. H. MUSSER and G. H. HAUSER (*Journ. Amer. Med. Assoc.*, April 21st, 1928, p. 1267) describe the post-mortem appearances of the brain in ten cases of encephalitis in measles. The gross changes consisted in extensive injection of the pia-arachnoid vessels and cerebral vessels generally. In one case thrombi were noted in the vessels of the pia-arachnoid. None showed inflammatory exudate over the surface of the brain, but there was considerable clear fluid in the sub-arachnoid spaces. The convolutions were flattened and the sulci shallow. On section the brain showed discrete punctate haemorrhages, with some areas of diffuse haemorrhage. Microscopical examination revealed perivascular haemorrhages round the small vessels, which appeared to be peculiar to this type of encephalitis. None of the cases showed any clinical or post-mortem evidence of tuberculosis or syphilis.

#### 664. The Optimum Hydrogen-ion Concentration for Giemsa Staining

J. G. LACORTE (*C. R. Soc. de Biologie*, May 25th, 1928, p. 1579) finds that the best method of differentiating *Trypanosoma gambiense* in guinea-pig's blood is to add one drop of Giemsa's stain to 1 cubic centimetre of a buffer solution at pH 7.4, and to place the film in contact with it for one hour. The buffer solution is made by adding acid sodium phosphate to distilled water. If the pH is below 7.4 the organisms and the blood cells appear reddish; if it is above 7.4 they become bluish. The best differentiation was obtained at pH 7.4.
